Death from Hiccoughs.—A well-known yet mysterious man in the person of H. H. Greyson died from the above cause, at the Pennsylvania Hospital, February 25th. Letters showed him to be the personal friend of Cecil Rhodes, Gen. Miles, and Gen. Wheeler. He had been postmaster at Manila and had been recommended for the Victoria Cross by Col. Baden-Powell. Nothing was left to tell of his birthplace or relatives.

Representation Asked by Women.—A committee of the students of the Women's Medical College has sent a petition to Mayor Ashbridge asking that that institution be represented on the examining board of the Philadelphia Hospital, saying: "Since our graduates are admitted to the examination for the position of resident physician in the Philadelphia Hospital, and since the other leading medical schools are represented on the Examining Board, we would respectfully urge a similar recognition for our College.

Rights of Christian Scientists.—The adherents of Christian Science in Lackawanna county are making a strong fight to extend their iniquitous practises. The little child of a business man in Scranton recently died from diphtheria after being treated by exponents of the faith cure. The parents then secured a regular practitioner to issue a death certificate and when the Coroner prepared to hold an inquest the Court was asked for an injunction to restrain him from so doing. The injunction was refused. A bill in equity has been filed, and the matter will be pushed to a decision.

Concession to Literary Colleges.—At a recent conference between the Medical Council of Pennsylvania and a committee representing the college presidents of the State the following action was taken by the Council:

"*Whereas,* the Act of Assembly requires that applicants must have pursued the study of medicine for at least four years, including three regular courses of lectures, in different years, in some legally incorporated medical college or colleges, prior to the granting of said diploma or foreign license; therefore, be it

"*Resolved,* that in the judgment of the Council, when the medical course of the literary college, as proven by the examination of the student by the medical college, covers the entire work of the first year of actual medical study, such course may be accredited by the medical college as the first year of medical study required by law."

Pennsylvania Hospital Clinic.—The patient suffering from post-typhoidal insanity, mentioned in our letter of last week, was shown by Dr. J. M. Da Costa February 24th, entirely recovered except for a slight degree of sleeplessness at night. The treatment consisted in forced feeding, stimulation by three ounces of whiskey daily, and the use of strychnine and syrup of hypophosphites. Statistics show that of 1288 cases admitted to the insane department of the Pennsylvania Hospital since 1883 there were only nine cases following typhoid fever. This includes only males. Of females the number was still less, the percentage being but one-tenth of one per cent.

Dr. Da Costa has collected more than a dozen cases of a not generally recognized type of simple continued fever. The average duration is from seven to ten days, the fever subsiding rapidly. A case or two has lasted as long as an attack of typhoid fever. The disease is believed to be fre-

quently mistaken by practitioners for influenza or abortive typhoid fever, although it is neither. The cause is probably a special bacterium or ptomaine, although investigations being made along this line have as yet failed to detect such specific cause.

College of Physicians.—At a meeting of the Section on Ophthalmology, February 20th, Dr. G. E. De Schweinitz reported a case of foreign body imbedded in the choroid for 18 years. No trouble was caused until three months before the patient presented himself. Then iridocyclitis was set up, and sight was nearly lost when the man was seen. Enucleation was done. The vitreous was found to be thin as water. An interesting query is what started the iridocyclitis at that particular time.

Dr. W. C. Posey presented a paper upon "Mental Disturbances after Operations upon the Eye," with the report of some twenty cases. Delirium, with hallucinations and ideas of persecution, was met with. A careful study of the causes was made. In nine cases in which both eyes were bandaged the bandage was removed from one eye when the symptoms began, but this was followed by no improvement. A predisposition to mental unsoundness as a cause was found to have no foundation in these cases, nor did the use of atropine or cocaine. The withdrawal of food and autointoxication were also eliminated from the list of possible causes, as sufficient nourishment had been given and the bladder and bowels carefully watched. The conclusion reached was that the cause in such cases is largely psychical and is due to preoccupation of the patient prior to and after the operation. The hope of having sight restored, the intense desire to help the operator by doing as he wishes, the rest and quiet brought by bandaged eyes after the operation—all these are intense and cause the disturbed mental state. A discussion of the subject showed a strong tendency among the members of the Section to attribute much of the trouble to the bandaging of both eyes.

CHICAGO.

Will of Dr. Holmes.—According to the will of the late Dr. Edward L. Holmes, recently filed for probate, an estate valued at $75,000 is to be divided among the relatives of the deceased.

Advice for Physicians.—The Chicago Health Department has issued a pamphlet for distribution by physicians, which contains advice regarding the importance of absolute isolation of cases of infectious disease. It calls for perfect ventilation of sick-rooms; the closing of all entrances save one; and the hanging of sheets wet with disinfectants over them is urged.

Mortality Statistics.—There were 504 deaths recorded during the week ending February 17th, being 27 fewer than the preceding week and 100 fewer than the corresponding week of 1899. Pneumonia claimed 105. Mortality from typhoid fever remains remarkably low. There were 567 births recorded during the week, an excess of 63 over deaths. There were 8493 pupils examined in the public schools, and 371 were excluded for fear of conveying contagion to the other pupils. Two hundred and fifty-two cases of contagious diseases were reported and 18 funerals of persons dead of sontagious diseases were supervised.

Chicago Surgical Society.—At a meeting held Tuesday, February 20th, the following officers were elected: President, Dr. John E. Owens; vice-president, Dr. D. A. K. Steele; secretary, Dr. Daniel N. Eisendrath; treasurer, Dr. S. C. Plummer; council, Dr. John B. Murphy, Dr. E. Wyllys Andrews, and Dr. L. L. McArthur.

Dr. A. E. Halstead presented a case of popliteal aneurism treated by ligation of Hunter's canal with subsequent incision of the sac. On January 18, 1899, under ether, the femoral artery was exposed in Hunter's canal and ligated with a double catgut ligature. The wound was closed and sealed with a collodion dressing. After this operation the pulsation immediately ceased in the aneurism, the leg was elevated, and external heat applied. In the course of a few days the aneurism became very hard, but still the pain and edema of the leg continued. Three weeks after the ligation of the femoral, when the danger of necrosis was considered passed, the aneurismal sac was opened and the clots turned out. The cavity was lightly packed with gauze and the wound allowed to heal by granulation. No hemorrhage occurred. The patient left the hospital one month after the second operation. His leg is in a good condition, the only effect of the aneurism being a slight flexion at the knee-joint.

Chicago Medical Society.—At a meeting held February 21st Dr. E. R. Le Count exhibited specimens and lantern-lides illustrating the pathology of medical affections of the kidney.

Dr. N. S. Davis, Jr., read a paper on "Diet in Nephritis," in which he said that nephritis can be produced experimentally by swallowing, inhaling, or otherwise introducing into the blood certain chemicals which are renal irritants, and which must be eliminated by the kidneys. Cases of Bright's disease of this origin are rare. Physicians occasionally see such poisoning by turpentine, mercury and lead. As a rule, however, the cases are due chiefly to infection and the elimination of toxins by the kidneys. The influence of overeating and on injudicious eating in producing chronic nephritis is so generally appreciated that it scarcely needs discussion. Chronic diffuse nephritis, like acute nephritis, is most often due to infection.

When a case of acute nephritis first comes under treatment it is best to enjoin rest in bed, to withhold all food for twenty-four or thirty-six hours, to give water freely and to empty the alimentary canal by provoking purgation. Milk should then be given, at first in small quantities, at intervals of two hours. The quantity must be increased gradually until two quarts are taken

daily. Milk is especially adapted as the sole diet of those who have acute nephritis because it more perfectly meets the demands of the system than any other single article of food. Intolerance of milk is often lessened or removed if, when a milk-diet is begun, it is administered in very small amounts, one or two ounces at a time, for example, and the amount is slowly increased. Milk, moreover, is less likely to produce gastric distress if it be sipped instead of being drunk rapidly. All things considered, it is the universal judgment of the profession that there is in this disease no substitute for a milk-diet. When the urine becomes copious and the amount of nitrogenous matter voided in twenty-four hours, all that can be expected, farinaceous foods may be prescribed in addition to milk. In a few days some of the sweet fruits and simpler vegetables can be given. When albumin disappears from the urine an egg can be tried. During the time that albuminous foods are being added to the patient's dietary, close watch much be kept upon the effect of it, the quantity of urine, the amount of daily nitrogenous excretion, the amount of albumin and number of tube casts, if any, found in the urine. When an egg can be taken without harm, white meats can be tried, such as the breast of squab and chicken, a small piece of boiled ham, or perfectly fresh fish. Red meats, rich in extractives, should not be eaten until recovery is established.

In chronic diffuse nephritis, there are the same indications for a milk-diet as in acute nephritis. It is, however, so prolonged a malady that an exclusive milk-diet cannot be maintained continuously. Interstitial nephritis is so chronic a malady that an exclusive milk-diet, even if it were necessary, could be maintained only for a small portion of its entire course. Zasiadko of St. Petersburg administered to ten patients, suffering from chronic nephritis, a vegetable diet for ten days, for a like period an animal diet (with a little bread added), and for another equal period of time a mixed diet. While upon a vegetable diet the amount of albumin in the urine lessened, arterial tension diminished, dropsy increased, the pulse became slower, weaker and softer, appetite failed, the patients became weaker and more apathetic. While upon animal food albumin increased in the urine, arterial tension rose, edema lessened, the pulse quickened and grew fuller, the patients became stronger and more cheerful. The effects of a mixed diet were midway between these. Alcoholic is looked upon as contraindicated in renal affections by the majority of clinicians. It is a renal irritant.

GENERAL.

Obituary.—Dr. H. R. Allen, a millionaire, widely known as a benefactor of crippled children, died while undergoing an operation at the Presbyterian Hospital, in Chicago, on February 13th. Several hundred crippled children, who had been treated by Dr. Allen, gathered in his offices in the Masonic Temple, in Chicago, to look upon his remains.

Conditions at Ladysmith.—A correspondent who escaped from Ladysmith February 10th reports that the continued diet of horse- and mule-flesh was getting somewhat monotonous although the health of the camp—taking everything into consideration—was better than could be expected; enteric fever and dysentery had abated, camp fever was slightly increased, but was not virulent. A local factory was turning out excellent horse sausages and another was making nourishing soup, which was much appreciated by the troops. The total number of men within the British lines was 17,000, all of them troops except 3000 civilians and 800 blacks. The live stock on hand included 4000 horses, 700 mules and 650 head of cattle. If there is sufficient forage for the live stock the danger of famine is certainly far off.

Denver's Consumption Victims.—The annual report of the Health Department of Denver, Col., shows that there were 536 deaths from tuberculosis during 1899, which were 31 more than during 1898 and 47 more than during 1897. Of 489 deaths from consumption in 1897, 88 were of patients who had contracted the disease in the State, and of this class there were 99 in 1898 and 58 last year. The increase in the number of deaths from consumption is attracting attention and a discussion of the situation occupies most of the space this year in the report of the State Board of Health. Already the danger from infection in the larger cities makes doubtful the wisdom of receiving patients in Denver, and the State Board calls for the immediate enactment and enforcement of drastic sanitary legislation.

Prenatal Injuries.—The Supreme Court of Illinois has handed down a decision in the case of an infant against St. Luke's Hospital, Chicago, in which it was sought to recover damages sustained by the plaintiff previous to his birth. Shortly before the birth of the child the mother was in St. Luke's Hospital, and while being transferred from one floor to another her left leg was caught in the elevator and crushed. When her child was born his left side and left leg were paralyzed and deformed. The mother settled with the hospital authorities on her own account and then brought suit for the child. The Court holds that at the time of the accident the child could not be credited as a separate being capable of sustaining an action independent of the mother. "If action can be maintained," it says, "it necessarily follows that an infant may maintain an action against its own mother for prenatal injuries."

The Sander Prize.—Rules for competition for the Gold Medal of the value of $100, dedicated by Mr. Enno Sander of St. Louis, for the best paper on "Military Surgery," presented at the Annual Meeting of the Association of Military Surgeons of the United States, are as follows: (1) Competition to be open to all members of the Association. (2) Each competitor shall send three copies of his essay, in a sealed envelope, to the Secretary, Lt.-Col. Chas. Adams, Central

Music Hall, Chicago, Ill., on or before April 15, 1900. The usual arrangement for secrecy regarding authorship will prevail. (3) The committee will designate the essay worthy of the prize, and also in their order of merit those deserving of honorable mention. Should the Committee deem proper, it may recommend neither prize nor honorable mention. (4) The successful paper shall be published in the Transactions of the Association.

Dr. Keeley Dead.—Dr. Keeley, the inventor of the "Keeley Cure" died at Los Angeles February 21st. The career of Dr. Keeley and his remarkable propaganda is one of the peculiar medical anomalies of the closing years of the century. Dr. Keeley in treating the mania for alcohol as a disease introduced nothing novel to medicine. On the contrary, he applied to the treatment of these cases a well-recognized method. Unfortunately, he threw about it a cloak of secrecy and tainted it with humbug and quackery, and brought it into prominence as a great financial scheme. Although at first it was attended with remarkable success, the financial feature proved its undoing. It must be admitted, however, that the Keeley cure has probably served a valuable purpose in disseminating among victims of alcohol a wide recognition of the fact that they are the victims of a disease. It has also indirectly promoted temperance by warning people of the danger of contracting an uncontrollable mania. As the vogue of the cure has gradually passed away, it has been replaced by methods of treatment having a reputable medical standing and supplied by regular practitioners.

The Plague.—The reports of the suppression of the plague at Honolulu, as stated last week, have been confirmed by despatches dated February 22d. Unfortunately, however, the disease has been introduced in the island Maui. This is one of the Sandwich Islands on which the immense sugar plantations are situated. The seven cases of plague discovered here were in the town Kahului which is the port of entry of the island. They all proved fatal, the victims being Chinese or Japanese. The same radical measures were adopted that had formerly been employed at Honolulu. A detention-camp was established and a careful inspection of all persons who had been in that section of the port known as Chinatown was instituted. Chinatown was then destroyed by fire. Investigation by the Board of Health showed that the disease was introduced to Maui through New Year delicacies imported from the Orient. On the day that these goods were opened the disease appeared. An effort is now being made to trace the remainder of this consignment. Three of the crew who handled the goods on the steamer which brought them were among the victims. One case has appeared at Hilo, which is the only port at which our transports from the Philippines have called since the outbreak at Honolulu.

The plague in India continues virulent. There were 583 victims in Bombay during the week ended February 16. With over 61,000,000 people affected by the famine and only about 4,000,000 in receipt of relief, India seems in bad plight, though the death rates over the 550,000 square miles of the famine area are decreasing. The Indian Government has issued a proclamation approving Professor Haffkin's anti-plague inoculation, and the Viceroy, Lord Curzon, is advocating its use throughout India.

Medical War News.—The following extracts of the diary of a correspondent at Kimberley give a striking picture of the hardships endured:

January 11.—Scurvy attacks the natives alarmingly. They are dying fast. The antiscorbutics are exhausted. Vine-cuttings are being tried in lieu of green food.

January 12.—Typhoid is very prevalent. Neglect to boil the water is the probable cause.

January 13.—Fifty typhoids in the hospitals.

January 16.—The military authorities have commandeered all the foodstuffs and other stores. Leave has been granted to the inhabitants to shoot small birds for food.

January 17.—The mules slaughtered are pronounced superior to horseflesh.

January 24.—Five hundred shells poured into the town, at haphazard, the hospital, scurvy-compound and residences receiving the attention properly due the defenders of the earthworks.

January 25.—A small family shellproof shelter has been dug in nearly every garden.

February 11.—Twenty-five hundred women and children were lowered into the mines throughout the night. The men are also selecting places of safety.

February 15.—Relief column arrived.

A well-known surgeon, discussing the character of the wounds received on the battlefields has pointed out that experience of the present campaign seems to show that the only absolutely fatal region is the heart. Bullet wounds of the brain are now not necessarily fatal, judging from the records of the last few weeks, and this is presumably due to the small size of the projectile, the velocity with which it travels, and the modern practice of scientific surgery, by which dangerous symptoms likely to arise from injuries may be warded off. It has, therefore, been suggested that, the heart being the only really vital part in the body, a steel covering should be provided, to be worn so as to protect that part from bullets. A steel plate might be attached to the soldier's tunics, and doubtless the small shield could be so fixed as neither to impede movement nor cause inconvenience.

At a recent medical examination of some Irish volunteers, who offered themselves for service in South Africa, two were found to have very bad teeth. Upon being told that this would be against their acceptance the first one remarked that he did not see why this should be against him because he had terrible hard gums, while the second one

remarked: "I thought we had to shoot Boers, I didn't know we were to ate 'em."

The British War Office for the first time has given out an official compilation of the British losses. The total is 11,208 to February 17th. This does not include, therefore, Lord Roberts' recent losses nor the Wiltshire prisoners. It is learned that the British losses at Koodoosrand were 700. Three thousand fresh troops embarked for South Africa February 20th.

CORRESPONDENCE

A CASE OF SALIVARY CALCULUS FROM THE SUBMAXILLARY GLAND.

To the Editor of the Medical News:

Dear Sir:—There has recently occurred in my practice a case of unusual interest to me from the fact that it was the first one of the kind that has ever come under my observation.

A young woman, twenty years of age, had complained for three days of pain upon movement of the tongue and jaws, and of a swelling underneath the tongue on the left side. On examination I found a lymph node, enlarged, tender, and movable, in the left submaxillary region. A portion of the sublingual gland of the same side was also swollen, and there was a decayed molar tooth in the lower jaw on that side. No digital examination of the mouth was made. The patient had had a mild attack of influenza during the previous week and it was thought that some infective process had been lighted up in the root of the decayed tooth.

The following day the inflammatory process had progressed, causing increased enlargement of the sublingual gland, the surface of which was excoriated. There was also increased swelling with tenderness of the submaxillary lymph node and induration of the floor of the mouth. There was a free flow of saliva. The speech was thick, and there was inability to open the mouth to any extent. Temperature was 101° F. The condition suggested some slight suspicion of Ludwig's angina.

Suppuration, with spontaneous rupture of the ranula, occurred the same night and a calculus was passed from Wharton's duct. The calculus was $^{11}/_{16}$ of an inch long and $^{3}/_{16}$ of an inch thick at the central portion, tapering to a rounded point at either end. A fine probe passed five days later showed the duct free from further calculi. It is needless to say the patient promptly recovered from her unpleasant symptoms.

S. H. Dessau, M.D.

New York, November 20, 1899.

STATUS OF MEDICAL PRACTICE IN PUERTO RICO.

To the Editor of the Medical News:

Dear Sir:—It gives me pleasure to give you some details of the practice of medicine as seen in this island.

The physicians in Puerto Rico have been, in the main, educated in Spain, the schools at Madrid, Barcelona, Cadiz, Sevilla, Valencia, Santiago, Valladolid, Granada and Saragoza, all being patronized. There are a few foreign diplomas on the island from the United States, France, Germany, Portugal, Switzerland, Belgium, Cuba, Scotland, Venezuela, Italy, Mexico, and Santo Domingo. From 1846 to the time of the American occupation, over 300 physicians had received licenses to practise in the island. Probably twenty physicians have come in since the occupation.

Those persons who studied in Spain do not commonly possess the title of "doctor," but are merely licensed "licensiado" to practise medicine and surgery. The explanation given for this is that the fees demanded for a diploma were so great poor students could not pay them. The persons who studied elsewhere than in Spain have, however, commonly the doctor's degree. For the registration of a foreign diploma the usual fee was 200 pesos ($150).

Besides the licensed physicians, there is a class of practitioners called "practicantes" or physicians' assistants, men who do the rough work in the mountains and among the poor. These persons are licensed to practise minor surgery, to pull teeth, and do whatever the physician under whom they practise may direct. From 1866 to date, 158 of these persons have been licensed. There are also midwives, called here "comadronas," who are licensed practitioners.

In the palace were registered, not only physicians and surgeons, but also surgeons major, surgeons second-class, surgeons third-class, surgeons, bloodletters, horseshoers, surgeon dentists, surgeon-practicos, surgeon-medico-practicos, medico-practicos, pedicuros.

Puerto Rico has a population of 975,000. There are now about 125 physicians on the island, or 1 to 8,000. The great portion of these are, however, crowded into the towns, leaving the country wholly without medical assistance, for the practicantes, like the physicians, are in the towns also. There are municipalities of from 10,000 to 20,000 population, which have to-day no physicians, because they are unable or refuse to pay for medical assistance for their poor.

The system has been as follows: Each municipality employs on a yearly salary one or more physicians to attend the poor. These physicians, if need be, give their whole time to the care of the indigent sick. Medicines are also provided by municipalities for the poor. Now it has come about, in time, that *all the people feel that they should have free medical treatment and free medicines.* The poor, because the law provides these things for them, and the well-to-do citizens, because they pay the bills. Hence, it follows that the doctor and the pharmacist have little private practise. The salaries paid medical men are miserably small, from 600 to 1000 pesos per year, or from $400 to 500, gold. Things have gone on along these lines, from bad to worse, until at the present time the practise of medicine is completely demoralized.

This is seen in the frequent removals of physicians, often three or four times in a single year. Since the great storm of August probably a score of physicians have abandoned their posts because their salaries have been temporarily stopped, leaving the distressed people wholly without medical assistance.

To look after the interests of physicians there existed under the Spanish Government a board called the Royal Subdelegation of Medicine and Surgery. To this body all diplomas were submitted for examination before a license could be issued for a person to practise medicine on the island. When written, the statement just made was thought to be correct, but it has since been discovered that persons received licenses from the Governor-General. How many of this class were granted is unknown. The considerations on which they were granted are also unknown. The subdelegation of medicine also examined and licensed dentists and practicantes. It settled disputes between physicians and advised the Government in all civil and criminal law-suits where expert testimony was desired. It was not, however, able to place the practise of medicine on a sound foundation in the island.

The subdelegation of medicine and surgery was abolished by General Henry, Military Governor. Its functions are now performed by a Superior (State) Board of Health. This Board is directed to issue a license to each qualified practitioner, respecting all existing rights of those established on the island. The following are the essential points in the order regulating the practise of medicine, pharmacy and dentistry now in force in Puerto Rico.

An examining committee of three physicians, two pharmacists and one dentist, is appointed to conduct examinations under rules formulated by the Superior Board of Health. The members of this committee must all be of ten years' standing and recognized ability in their professions, and all must speak English. The Superior Board of Health appoints the president and secretary of the examining committee. The examinations are all to be in writing. The results are to be submitted to the Superior Board of Health.

Licenses will be issued to the successful applicants by the Superior Board of Health. The fees for examinations are: For physicians and surgeons, $25; pharmacists, $25; dentists, $25; practicantes, $15; professional nurses, $10; midwives, $5.

Persons who violate the order may be punished by both fine and imprisonment.

There are no poorhouses in Puerto Rico, but most municipalities have one or more "hospitals" to which the bedridden poor are taken. They receive little medical attention, almost all hospitals having as attendants practicantes, who often leave their charges nearly uncared for. When a patient dies, the vacant bed is quickly occupied by another waiting unfortunate. These people live carelessly and die easily. Alive and well one day and dead the next is no uncommon occurrence. Of hospitals, as these institutions are known in the States, there are very few in Puerto Rico, except those belonging to the army.

The mountains of Puerto Rico are extremely inaccessible, roads being almost unknown, but they have a rich soil and are densely populated. For physicians to visit the sick in their inaccessible mountain homes is almost a physical impossibility. Hence, they often die unattended by even a practicante.

In practise the native physicians temporize and use expectant remedies only. This is true of all, no matter where educated. In surgery it is the same way. They do only what is absolutely necessary. Heroic measures are wholly unknown in their practise. With many physicians the treatment is rest in bed with milk or other light diet. With their people, it must be said, they meet with fair success in many diseases. The drugs-stores throughout the island are clean and well-stocked, very creditable institutions indeed.

Christian Science practise has not yet invaded the island, but spiritualist practitioners are numerous. Of these there are two classes. The first receive revelations which aid in diagnosis and treatment from the world of spirits indiscriminately. The second class practise in the names of dead physicians of local repute, receiving from the spirits of the dead doctors very excellent prescriptions, so the people say. To the credit of the established church, these people are outside its membership.

Just now the island suffers from tropical dysentery and anemia, hundreds of persons dying each week of both of these diseases, which, however, confine their ravages to the poor who have but little food, clothing or shelter. The sanitarian meets with the greatest difficulty in his work. After a death it is a custom to hold religious services, for a period of eight days, in the room where the death occurred. No other room will answer the purpose, even in cases of contagious diseases. Many of the poor bathe very seldom and treat open sores with a decoction of urine and tobacco. There are probably 100 lepers on the island, but the disease does not tend to spread. Efforts are being made to collect all these unfortunates into an isolated locality where they can be well cared for.

Ending June 30th, 800,000 vaccinations were performed, and for several weeks past not a single case of smallpox has been known to either the civil or military authorities, showing clearly the possibility of controlling this disease in a Spanish-American country. Not a case of yellow fever appeared in the island all summer, indicating that that disease is not endemic here.

George G. Groff, M.D.

Secretary and Treasurer, Superior Board of Health.
San Juan, P.R., December 25, 1899.

Degenerates Exterminated.—Dr. McKim of New York in a recent book, recommends that the State should consign the hopelessly insane, the degenerate, etc., to a lethal chamber.

TRANSACTIONS OF FOREIGN SOCIETIES.

German.

AORTIC ANEURISM WITH FEW SYMPTOMS—CONGENITAL HERNIA OF THE DIAPHRAGM—NATURE OF RELAPSE—SURGICAL TREATMENT OF RENAL TUBERCULOSIS—FINAL RESULTS OF GASTRO-ENTEROSTOMY—SUBPHRENIC ABSCESS — CARDIAC DYSPNEA AND PULMONARY EDEMA—OPERATIVE PERFORATIONS OF THE UTERUS.

AT the Union for Internal Medicine, January 15th, VON LEYDEN showed the specimen from a patient who had died from aneurism of the arch of the aorta. Curiously, no tumors, pulsation, murmur nor cardiac hypertrophy could be made out during life. There was observed only a paresis of the left vocal cord, followed by attacks of dyspnea and a marked respiratory stridor, due to compression of the trachea. The suspicion of aneurism was confirmed by a radiograph. The normal respiratory murmer was lessened not only on the left side where the pressure was on the bronchus, but also on the right side on account of insufficient inspiration. Seven injections of a solution of gelatin were made, but they had no apparent good effect. Death resulted from suffocation.

BRUSA spoke of a boy aged eight years, who had a congenital hernia of the diaphragm. The left lung was crowded almost out of its cavity by the protrusion into it of many of the intestinal loops, etc.

LIPPMANN discussed the question of relapse. In a five-year-old boy the decrease in size of a cervical lymph gland was followed by a relapse of scarlet fever. There is probably no such thing as a reinfection in scarlet fever, but only relapse starting from some remaining focus. Similarly in erysipelas there often remains a nest of cocci in the lymph channels which may lead to a further outbreak of the trouble. Follicular tonsillitis does not develop after the removal of the tonsils that harbored the germs. In furunculosis the cause of relapse is to be found in the remaining infiltration of the skin. Apparently new infections are often shown to be relapses by the fact that (1) the exanthem appears in the neighborhood of swollen lymph glands; (2) the course of the disease is mild; and (3) it is not the disease itself, but an etiologically allied trouble which develops. The germs of infection may remain encapsulated in parenchymatous tissues for years. Osteomyelitis, for example, may produce new foci after a lapse of decades. Usually the germs are freed from their capsule by a traumatism or an operation, on exposure to cold, or a psychic irritation with increase of blood pressure may suffice for their liberation. Puerperal fever is not always due to germs introduced from without. It may develop from old uterine or periuterine gonorrheal inflammation.

KONIG spoke of the surgical treatment of renal tuberculosis. This disease appears in two forms, *viz.*, either in small solitary nodules of the cortex which are recognized with difficulty, or as an affection of the pelvis of the kidney, which may be recognized without the demonstration of the tubercle bacillus in the urine by a train of symptoms—cloudy urine, unilateral renal pain, flocculi in the urine which are composed of epithelium of the pelvis and pus-cells. Later a tumor is palpable and the patient becomes emaciated and anemic. Resection and drainage are useless procedures. Removal of the whole kidney is the only chance of recovery for a patient having this form of renal tuberculosis. The existence of an opposite kidney must first be determined. Congenital absence of a kidney is associated with absence of the corresponding testicle. Catheterization of both ureters and analysis of the urine are absolutely necessary and entail no risk if properly performed. König has performed nephrectomy 20 times for renal tuberculosis. Twice the diagnosis was erroneous, the smegma bacillus having been mistaken for the tubercle bacillus. Of the remaining 18 patients, 3 died of anuria, and at autopsy the epithelium of the remaining kidney was found to be extensively necrotic. Consequently König no longer uses chloroform upon such patients, and keeps all antiseptics out of the wound. A moderate affection of the opposite kidney, nodules in the prostate or testicles, and disease of the bladder are not contraindications to operation. They tend to disappear when the chief source of infection and irritation has been removed. Six of the 18 patients (12 women, 6 men) operated upon died soon after operation. Eleven were living after periods of two, nine, six, and a less number of years.

LITTEN called attention to a third form of renal tuberculosis, characterized by a general caseation, with obliteration of the ureters. He showed two specimens.

At the Free Union of Surgeons of Berlin, January 8th, MERKENS spoke of the final results of gastro-enterostomy, mentioning 23 cases in which Murphy's button had been used. Six of the 7 patients who suffered from benign stenosis recovered. Sixteen patients were carcinomatous; 5 of them died within a month of the operation; 7 within two months; 8 within three months; 9 within five months; 11 within seven months; 12 within a year. The remaining four patients were alive at the time of report, one having survived the operation two and a half years. Posterior gastro-enterostomy had been performed, without entero-anastomosis and symtoms of a vicious circle had not appeared.

REICHERT showed a patient aged sixty-eight years who had washed his stomach two or three times daily for twelve years on account of dilatation and fermentation. Gastro-enterostomy was performed upon him and in six months he gained twenty pounds.

WEBER examined the records of 600 cases of appendicitis, and found that subphrenic abscess had occurred only nine times 2.15 per cent.).

Seven of these nine patients were operated upon. Three died and four recovered. Such an abscess may follow appendicitis in three ways, *viz.*, the infection may travel upward along the ascending colon, or retroperitoneally, or the appendix itself may lie extended upward.

Karewski mentioned two instances in which subphrenic abscess was due to trauma. Once it followed osteomyelitis of the eleventh and twelfth ribs of traumatic origin, and once it developed in a little girl who had been run over by a wagon. The pus in the latter case was sterile, and in it was floating the necrotic spleen. The abscess cavity was opened through the pleura.

Korte reported 35 cases of subphrenic abscess, 16 of them being of appendical origin. He prefers the perpleural operation. Twenty-three of the 35 patients were cured. In the pus micro-organisms were always found.

At the College of Doctors, Vienna, January 22nd, v. Basch spoke of cardiac dyspnea and pulmonary edema. Physiology understands by "dyspnea" the accumulation of increased respiratory stimulus. Clinically in dyspnea there appears to be a disproportion between the respiratory effort and the result. The cause of dyspnea in cardiac complaints is said to be either the irritation caused by the carbonic dioxide or the lack of oxygen. Traube explains it on mechanical grounds by saying that in congested lungs the capillaries are distended and twisted and project into the alveoli and so cause a mechanical obstacle to respiration. As to the result of his experiments, Basch became convinced that the essential factor in cardiac dyspnea is obstruction of respiration. For instance, if a manometer is placed in the trachea and fluid is then injected into the trachea, it is at once evident that the lungs increase in size. If the alveoli of a lung are filled with blood, the lung does not follow the excursions of the thorax as readily as before, for it has become stiffer and larger. Swelling and stiffness of the lung are the real factors of cardiac dyspnea. If a person whose heart is not badly affected remains quiet he can breathe easily, but when he makes some effort the lungs become stiffer and so do not answer the demands made upon them. The feeling that one cannot get enough air is increased to the highest grade in asthmatic attacks. These usually come on spontaneously, but they may be brought on by muscular exercise or excitement. The practical treatment is to give no emetics nor expectorants, but such remedies as will strengthen the heart (digitalis, camphor). Morphine, too, may be of value to lessen the blood pressure and so lighten the work of the heart.

At the meeting held January 29th Braun v. Fernwald spoke of perforation of the uterus in gynecological operations. Usually the accident occurs during excochleation and the removal instrumentality of placental remains. When one is operating aseptically perforation of the uterus by a sound is not dangerous, and has been doubtless overlooked many times, causing no symptoms. For curetting a large dull instrument is recommended. Placental remains should be removed by the fingers as far as it is possible to do so. The condition of the uterine wall has a great deal to do with the occurrence of perforation. The puerperal uterus, especially if septic, can easily be perforated. The treatment of perforation consists of rest in bed. If there are alarming symptoms in septic cases, it is desirable to extirpate the uterus through the vagina. If a perforation is suspected irrigation must not be used. Bleeding may be stopped by packing gauze into the uterus. If intestine appears through the perforation, laparotomy should be at once performed in order to make sure that the intestine is not injured. In one case there were no less than six perforations, but the patient recovered without any complication.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.—SECTION ON PEDIATRICS.

Regular Monthly Meeting, Held February 8, 1900.

Thomas S. Southworth, M.D., Chairman.

Dysentery from Bits of Wool.—Dr. LaFetra presented a specimen from a child who had suffered from sudden high temperature with diarrhea. The specimen had been obtained from several successive irrigations of the colon. A number of particles of some material resembling absorbent cotton were found in the stool. The mother denied that the child had had the opportunity to swallow any absorbent cotton. She recalled, however, that the child had the habit of picking at the fluffy material of its cradle coverings. Material thus plucked off it would put into its mouth. It is evident that the child swallowed a considerable amount of this material, which collected in the large intestine. During its course through the intestines it set up irritation, interferred with digestion and led to the absorption of toxic substances from the intestinal canal, thus causing the symptoms. When first seen the child had a temperature of 104° F., and it had a convulsion that lasted about five minutes followed by a period of unconsciousness lasting about the same length of time, an hour or so before it was seen. Because of the convulsions the child was treated by a hot pack at first and because of the temperature by a cold pack at 72° F. Shortly after the cold pack was applied an evacuation took place which contained some portions of the cottony material. The rest of the material was then removed by irrigation. Since then the child has been improving. The child had been perfectly well previously and although four teeth were irrupting on one side of the mouth, two upper and two lower, there seems no good reason to

think that this would be sufficient in a healthy child to cause the symptoms noticed.

Carbonic Acid Gas for Whooping-Cough.—Dr. N. R. Norton reported two series of cases of whooping-cough occurring in two different years, treated by rectal injections of carbonic acid gas. Out of 150 patients, 143 were benefited to a very noticeable extent. After the injections vomiting ceased and the paroxysms of coughing were less frequent and less severe. The seven cases that were not benefited were of weakling children in advanced stages of the disease. The carbonic acid was obtained from a mixture of bicarbonate of soda and crystals of tartaric acid. By this method the gas is given off sufficiently slowly, so that its administration may be kept up continuously for the necessary length of time. In infants the injections were given for five minutes at a time; in older children for ten minutes. The administration of the carbonic acid gas is followed by flushing of the skin, especially of the face. In a few of the patients mild diarrhea developed. This seemed to be produced by the irritation of the rectal tube. It ceased after a day or two, when the injections were discontinued, and they could usually be resumed a day or two later without necessarily causing the diarrhea. As children suffering from whooping-cough frequently have diarrhea it is doubtful whether the carbonic acid or the method of administering it was the cause of the frequency of stools.

The success of the injections of carbonic acid gas was marked only when the nascent gas was employed, that is to say, when the gas was obtained fresh from the chemical reaction of the bicarbonate of soda and the tartaric acid. In a series of twenty cases, in which commercial carbonic acid gas was used, it seemed to have absolutely no effect on the whooping-cough. By commercial gas is meant that which is obtained in tanks from the manufacturers of soda-water supplies. This does not seem to have the same chemical activity as the freshly prepared gas which acts as if in the so-called nascent state.

Intubation for Whooping-Cough.—Dr. O'Dwyer at the time of his death had been working for some time on the question of relieving severe cases of whooping-cough by means of the laryngeal tube. In some notes that he left on the subject he says that the torture which causes the child to drop its toys and fly to its mother or the nurse when a paroxysm of whooping-cough is about to come on must be felt personally to really be appreciated. He had whooping-cough himself when over forty and said that the spasm of the glottis which accompanies it gives one a sense of intending death which no amount of reasoning can remove. To relieve this torture it seemed to him for a long time that intubation would be effective. For this purpose he suggested, not the metal tube which is liable to calcareous incrustation with the production of sharp, roughened points which irritate the laryngeal tissues, but the hard rubber tube which remains clean and absolutely smooth for long periods. Intubation undoubtedly relieves the spasm. Some time ago at the Foundling Hospital three cases of whooping-cough developed laryngeal diphtheria, and intubation became necessary. It was interesting to watch the result of the intubation on the whooping-cough. There were all the usual symptoms of the expiratory spasm, but no inspiratory difficulties and no vomiting although the children had frequently vomited. It would seem, then, that in severe cases, at least, in which the child's nutrition suffers because of the vomiting, intubation is indicated.

Whooping-Cough in Dispensaries.—Dr. Walter A. Dunckel read a paper in which were discussed all the cases of whooping-cough that have been treated at the New York Dispensary during the past five years. About sixty per cent. of the cases were in females. Fifty-eight per cent. of the cases occurred between six months and four years. Only two of them occurred at three months, and none of the cases were over twenty years of age. The complications usually occurred in children under three years of age. Between the ages of three and four complications were notably less and after five they became comparatively rare. The great majority of the complications occurred from the eighth to the tenth week of the disease. Four of the cases lasted three months, one case lasted four and one-half months, while one case lasted but two weeks. In one case empyema developed and was operated on during the course of the whooping-cough. The paroxysms of the disease seemed to help in the expansion of the lungs. Although the child was so weak that it was feared it would not outlive the operation, it recovered completely. It might be thought that emphysema would develop because of the intense respiratory effort required during the spasm of the glottis. Although it was carefully looked for in all the cases that could be followed for any length of time it developed only in two patients, one boy and one girl. Pulmonary tuberculosis is not frequent after whooping-cough. It seems that the intense expiratory effort after the paroxysm throws the bacilli out of the air passages. The bronchopneumonia seems in many cases to be really tuberculous in character. Notwithstanding this consolidation of part of one of the lungs does not absolutely mean a bad prognosis. A certain number of cases clear up and the children recover. A certain number of cases of cardiac disease develop after whooping-cough, in which the latter disease would seem to be the etiological factor. No endocarditis and no murmurs, however, can be found.

Treatment.—Belladonna given to its full physiological effect seems at times to give good results. Cod-liver oil is of decided benefit. This is especially manifest from the fact that mothers come back regularly to demand the "thick medicine." Antipyrine cannot be used to advantage in dispensary practice. It seems risky to push the drug to the extent to which it must be used to secure good results, except where patients are constantly under the care of a physician. Bromo-

form was not used because of the uncertainty of its mixture and because there was very little confidence in the remedy. Dr. Huddleston while in charge of the dispensary had used bromoform in a number of cases and had never seen any but doubtful good effects from it. As a matter of fact the prognosis in cases of whooping-cough depends largely on the hygiene of the patient's surroundings. Where an abundance of good food, good air, and careful nursing is provided fatal terminations are rare and complications of any serious character occur but seldom.

Comparative Drug Values.—Dr. Chas. G. Kerley read a paper descriptive of a series of efforts to determine by actual observation what drugs were most efficient in the treatment of whooping-cough. The cases were taken in groups of twenty and were allowed to run their course untreated to the acme of the disease. Charts were made of the number of paroxysms that occurred and of their severity. When there was no increase in either the number or severity of the paroxysm for three days the disease was then considered to be at its height and the drugs chosen were administered. The age of the patients varied from three months to twenty-six years. There were only three adults and five-sixths of the cases were under four years. Many cases of whooping-cough in private practice are mild and do not exceed five to six weeks in length. Recently Dr. Kerley has had a boy who had altogether only three paroxysms during the course of the disease, but these were typical enough to make the diagnosis sure. His sister had all the catarrhal symptoms of whooping-cough but did not whoop once. In hospital practice, however, it is no unusual thing to have cases to go on for ten weeks, for three months, or even longer. The observation of the effect of the remedies on these cases seems best calculated to bring out the true therapeutic effects of the drugs if there are any. Vapo-cresolin was tried in ten cases, but did not seem to produce any effect. This drug seems best for mild cases in private practice because of its suggestive effect on nervous parents. Inhalations of turpentine and steam were tried. They seemed to have but very little effect. Alum seemed to be of some service, but had such a bad effect on the stomach that after five days it was discontinued. Fluid extract of chestnut leaves and dilute nitric acid seemed to produce no effect on the disease at all. Bromoform was tried in sixteen cases, but seemed to be of no service. Only three of the cases were relieved and the remaining ones seemed to be absolutely unaffected by the drug. Spraying with cocaine, three per cent. solution, was tried in twenty-six cases. It seemed to be of some value. Quinine when pushed was found to be of great service. Twelve to twenty grains must be used in the twenty-four hours to produce the desired effect. It was very faithfully tried in sixty cases, so that the result seems to be very trustworthy. The drug is not palatable, however, and it is difficult to make it so. When given in this quantity neither chocolate, yerba santa, nor thick syrup succeed in disguising the taste. Their use as vehicles serve but to disturb the stomach. In older children it may be given in capsules. One difficulty of its use in private practice is that parents are apt to object to it if given in the doses it should be to have any effect. Belladonna is recommended by practically all the text-books as a specific for whooping-cough. It was tried in sixty cases to its full physiological extent without the slightest effect. It is a striking lesson in the trustworthiness of text-books, to see a child with typical dilated pupils and the belladonna blush having characteristic paroxysms of whooping-cough. The bromides, given in doses of twelve to sixteen grains daily in raspberry syrup, were found to lessen the severity of the paroxysms, although they did not decrease their number. Antipyrin was used in sixty cases. It controlled the paroxysms both as regards severity and number better than any other drug. In all cases where it was given it caused improvement. Antipyrin is a drug easy to administer. The best effect is obtained by combinations of the bromides and antipyrin. To a child of eight months one-half grain of antipyrin and two grains of bromide may be given every two hours until six doses have been taken. To a child of twelve months, one grain of antipyrin and two grains of bromide may be given every two hours for six doses. To a child of two years, two grains of antipyrin and three grains of bromide may be given in the same way. After the sixth dose an intermission of twelve hours should be allowed in all cases.

Steam in the room, keeping the air moist, is very effective in reducing the severity of the paroxysms. An Arnold steam atomizer is very efficient for this purpose. Steam medicated with creosote and turpentine was used, but it is doubtful whether it is any more effective. It is often said that children do not cough so much while they are out in the air. Mothers of the poorer class are apt to tell the doctor that the children do not cough on their way to and from the gas-tank, the gases from which are supposed to be good for the disease, the children being brought there every day. Because of the fact that it takes the children out into the air the gas-tank treatment should be encouraged. The paroxysms are usually worse at night. The cause of this is often the want of fresh air. The remedies that surely do good in whooping-cough are the sedatives and fresh air. It must be remembered that patients become accustomed to any drug and a change may be required.

Antiseptics in Whooping-Cough.—In the discussion Dr. S. H. Dessau insisted on the value of antiseptics in the treatment of whooping-cough. The disease is due to a specific germ and it is to be expected that an antiseptic is indicated. The paroxysms partake besides of a nervous explosion so that a sedative would seem to be indicated. Chloral besides being a sedative is a good internal antiseptic. For a number of years Dr. Dessau employed the drug rather freely, but stopped using it because it is a most nauseous prepara-

tion. Undoubtedly antipyrin owes some of its value as a remedy for whooping-cough to the fact that it is an antiseptic as well as a sedative. Recently in Germany a new remedy has been employed which is also an antiseptic, *viz.*, difluordiphenyl. It is used by inunction, a five per cent. ointment of lanoline and vasoline being rubbed into the chest and back after a free cleansing by sapo viridis. Benefit is claimed from this treatment after two days and cure in two weeks. Some time ago Cadet Gassicourt suggested that the whoop of pertussis might be due to enlarged mediastinal glands pressing upon the recurrent laryngeal nerve. He attributed the enlargement of the glands to the presence of tubercle bacilli. There seems no doubt that there are cases in which the whooping-cough is really due to such a condition as Gassicourt describes. In these cases belladonna and potassium iodide are valuable.

Dr. G. M. Swift said that the value of antiseptics in the treatment of whooping-cough has been impressed upon him of late. The air of the room in which the little patients are confined can be rendered medicinal in its effect by keeping a 25 per cent. solution of formalin constantly exposed in an open vessel. This is quite sufficient to make the odor of the drug noticeable in the room. This same expedient is useful in influenza. For the treatment of whooping-cough fresh air is of the greatest importance. There are undoubtedly some cases in which the mediastinal glands are demonstrably enlarged and in which this enlargement has something to do with the paroxysmal cough. In these cases an abundance of fresh air is a most useful remedy. Dr. Swift has a prejudice against the coal-tar products, although at times he has seen some good come from phenacetine. He has seen good effects from heroin in a certain number of cases and has been pleased with its action. It seems to replace codeine very advantageously although, of course, its real value is not yet decided.

Dr. J. J. Walsh said that it is a tradition in the mining districts of Pennsylvania that the air of the mines is good for whooping-cough. In order that children may have the opportunity to breathe it they are taken down in the mines for some hours several times a week. The custom has practically been discontinued of late years, because medical men scoffed at the idea. As a matter of fact it is very probable that the fresh air that the children enjoyed during their excursion to and from the mines, together with the hour in the mild, equable temperature of the mines, which is never above 70° F. and never below 60° F., was not without its effect. Dr. Walsh mentioned that a series of cases had been treated recently by serum taken from individuals who had had whooping-cough. It is well known that whooping-cough protects very well against second attacks for years after a first attack of the disease. It is to be presumed, then, that according to modern ideas of immunity the serum of a person who has recovered from an attack of the disease contains for life certain properties which make it efficient against the germ of the disease, for whooping-cough is undoubtedly a germ disease. This fact of immunity was taken advantage of in some recent experiments for the treatment of the disease. When injected into children suffering from whooping-cough this had the effect in two cases of aborting the disease and in others of lessening the number and severity of the paroxysms. The subject is as yet under investigation and the experiments have not been definitely published.

Dr. Hermann said that for the past two years Dr. Koplik has found the sedative coal-tar products, especially antipyrin, of the most use in the treatment of whooping-cough. It is given to a child of two years in two-grain doses guarded by a drop dose of digitalis.

Dr. Walter Lester Carr said that the most satisfactory remedy for whooping-cough seemed to be antipyrin with codeine. Codeine has not been replaced in his experience by heroin. Quinine is good mainly because it acts as a tonic. Fresh air is extremely important and the children's playroom should be freely aired and its windows kept open practically all the time. It is not alone the paroxysms of whooping-cough that must be treated, but the while mucous membrane of the patient. If adenoids and hypertrophied tonsils exist they should be seen to early in the case. In a word, it is the patient and not the whooping-cough which must be treated.

Dr. Berg said that whooping-cough has two indications for treatment: First, the convulsion, and, secondly, the softening of the tough glairy mucus which makes the paroxysms persistent. For the convulsion, just as for epilepsy, the bromides are the best drugs. For the softening of the tough secretion bichloride of mercury is very effective. Years ago before the introduction of the antitoxin method of treating diphtheria most practitioners had favorable experience with the success of the soluble preparations of mercury in causing the disappearance of throat secretions and membranous deposits. It will do this in whooping-cough also. One-sixtieth of a grain may be given every three hours to a child until diarrhea occurs, then intermitted for several days and taken up once more when the child's stools have become normal in number and amount. Under this treatment complications by severe bronchitis or pneumonia are very rare.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held Thursday, February 15, 1900.

The President, Wm. H. Thomson, M.D., in the Chair.

The business of the evening consisted of a discussion on the etiology of cancer as far as light had been thrown upon that important subject by the work of the past year in the New York State

Laboratory for the Investigation of the Cause of Cancer at Buffalo.

Cancer Etiology.—Dr. Roswell Park said that his remarks on this subject at the present meeting were but a supplement to a paper that was read before the New York State Medical Society at its recent meeting in Albany. (See p. 324.)

Karyokinesis, he said, is not now looked upon as so important a feature of cancer as it formerly was. Arnold has called attention to the fact that fragmentation takes place in portions of a malignant tumor and that this seems to be characteristic of certain grades of malignancy. A Japanese pathologist, however, considers that this fragmentation is a post-mortem change; Klebs has recently called renewed attention to leucocytic inclusion in cancer. In this respect cancers are comparable to the infectious granulomata. It would seem that this inclusion was due to phagocytosis and supposes the presence of parasites.

The question of metastasis continues to be a most interesting one. Each metastasis is really to be considered as an autoinfection. Under varying circumstances metastases are very specific in character. From certain organs they almost invariably take place in certain definite tissues and not in others. Von Rechlinghausen pointed out a good while ago that metastasis from cancer of the prostate is practically always to be found in bone. While metastasis from cancer very seldom takes place in the lungs that from sarcoma is quite frequent. It occurs by means of retrograde venous embolism or by direct infection from particles in the venous blood stream.

Conveyance of Cancer.—Certain forms of communication of cancer are very familiar. That it may pass from one lip to another has long been well known. In recent years we have learned that one vocal chord may infect the other. Cases of communication of cancer from the eyelid to the globe of the eye have been reported. In a number of cases we know that a carcinoma of one wall of the bladder has led to infection of the opposite wall from the two surfaces lying in contact. The same thing happens with regard to the stomach. A still more notable example of cancer infection is when cancer develops in the stomach from the swallowing of portions of cancer tissue from a cancer focus higher up in the esophagus. A striking case has been reported recently in which a patient who had cancer of the ear scratched it and thus infected his lip. Cancer of the lung from cancer of the larynx has been reported and is evidently due to the same process as leads to the infection of the stomach from the esophagus.

Vitality of Epithelial Cells.—The epithelial cells in cancer not only retain their vitality to be carried from one part of the body to another, but seem to retain it for some time after removal from the body under favorable conditions, as in serous fluids and the like. The failure even by the most distinguished experimenters to inoculate cancer only shows that the methods thus far employed have been wrong. It does not inevitably lead to the conclusion that we will never be able to solve the mystery of cancer infection. There are certainly some cases on record in which cancer has been conveyed to animals. A number of cases in human beings show that the persistent irritation of epithelial cells with opportunities for infection may lead to the development of cancer. Cases are frequent in medical literature in which cancer has developed in the scar of lupus vulgaris. It does not develop after lupus erythematosus. It frequently develops in fistulous tracts, especially fistulous tracts leading inward, as down to a necrotic focus in bone disease. It develops not infrequently in urethral fistulæ. The scars of burns are in the same way frequently the site of cancer.

Irritation and Cancer Development.—Volkmann found that out of 126 cases of cancer of the limbs 99 were due to irritation. The well-known effect of irritation in producing cancers around the mouth needs scarcely be mentioned. Jagged teeth, the presence of tartar, the use of tobacco, all have been set down seemingly with good reason as predisposing causes of cancer. Debove reported cancer of the tongue in 24 cases out of 25 cases of psoriasis that he had had under observation. The process recalls vividly Paget's disease of the nipple and the liability to cancer that follows it. Cancer of the genital organs is also frequently due to chronic irritation. Psoriasis uterina has been reported as preceding cancer of the body of the uterus. Cervical cancer follows the use of a pessary or occurs in the scar of a laceration of the cervix or at the site of an old ulcer. Cancer of the bladder occurs after a vesical calculus and cancers of various parts of the urinary tract have been traced to the irritation of calculi at various points in the kidney and its pelvis. Biliary lithiasis is undoubtedly at least a predisposing cause of cancer of the gall-passages. Epithelioma has been reported as developing in the wall of a cavity in the lung and in the indurated tissue around a tracheotomy tube. Endotheliomata have occurred with great frequency among the workers at Schneeberg in the cobalt mines. It occurs in the lungs from inhalation of the irritating metal dust of the mines.

Cancer Dyscrasia and Cachexia.—Cancer dyscrasia often precedes the development of cancer. It has often erroneously been thought to be a consequence of its initial steps. It would seem, however, that the system gets into a condition in which the development of cancer is favored by the lowered nutrition of the patient. The condition cannot be described as accurately as can the tuberculous dyscrasia, but it undoubtedly exists. Cancer dyscrasia and cachexia must not be confounded. The cachexia develops as a consequence of the drain upon the system by the growth of the tumor and by the absorption from it of certain toxic substances that disturb systemic metabolism. The injection of cancer juice into animals always produces serious results; fever develops, salivation occurs, and collapse closes the scene. There is undoubtedly great toxicity

in cancer serum. Coma has been known to develop in a number of cases in which there was rapid softening of the cancer with absorption from the tumor of a considerable amount of cancerous elements. This coma is not unlike the similar condition which develops as the result of diabetes mellitus. Klemperer has reported the discovery in the blood of cancer patients of oxybutyric acid which is thought also to be the important element in the production of diabetic coma.

Cause of Cancer.—Dr. Gaylord said that the most important work on the etiology of cancer in recent years has come from the Italian school. The daily press gave a good deal of space not long ago to the work of a Frenchman who reported that he had discovered the cause of cancer. He was undoubtedly only a charlatan, however, and his supposed specimen of the cause of cancer proved to be nothing more than a very ordinary form of rose yeast. His cancer serum was a fraud.

Blastomycetes in Cancer.—The most important studies in the etiology of cancer at present are those that concern themselves with the blastomycetes or yeasts. Their possible connection with cancer was first suggested by Roncali, who, while studying certain appearances that were supposed to be coccidia, recognized that they were yeasts. Before this Russell of Edinburgh had pointed out the almost invariable presence in cancer of certain "fuchsin bodies," so called because they stain deeply with fuchsin. Russell thought that they were the cause of cancer. Fuchsin, however, stains a good many other things besides these bodies, and so it was not long before Russell's work on the subject was discredited by the observations of others. Russell was not, however, altogether wrong. The problem is not one that can be decided by morphology alone. The microscope is not sufficient to decide and we shall not know definitely until we are able to tell something more of the internal structure and mode of development of these bodies. Later on Ruffer and Walker and then Ruffer and Plimmer made similar discoveries. Plimmer found in 1100 out of 1200 cases of cancer a typical body that he considers a parasite. He did not succeed in inoculating this into animals. The body seems to be a blastomyces.

English and Italian Observations.—San Felice, who accepted Roncali's suggestion as to the possibility of blastomyces being the cause of cancer, has done considerable work on the subject. He has lately succeeded in producing by the inoculation of saccharomyces local tumors followed by enlargement of the lymph nodes. These lymph nodes were allowed to dry and when pulverized and inoculated into successive animals they became more and more virulent until finally they produced death in two days. The inoculation of this virulent material produced in one animal true adenocarcinoma of the breast. From this, however, the organism could not be cultivated, but it could be found in the tissues although in slightly modified form. It had become changed into something that was very like the Russell fuchsin bodies. San Felice succeeded in producing one cancer besides a series of other tumors. The latter were not typical of any single class, although one of them looked very much like a sarcoma. The possibility of the cultivation of the blastomyces from these tumors was very variable and seemed to follow no definite rule.

Pathogenic Yeasts.—Very little is known of the pathogeniety of yeasts. Busse in 1893 first showed that yeasts could be pathogenic for man. They occur mostly in skin lesions. The place of yeasts in botany is rather indefinite. Brefield unsettled the botanical world some time ago by announcing that a plant which grew in one cycle of its existence as a fungus, he had observed to grow in another cycle as a yeast. We have no way of classifying yeasts morphologically and the whole subject is extremely obscure. It is clear then that their possible connection with cancer can not be definitely made out for some time to come. We have evidence now which seems to demonstrate that the appearances found in epithelial cells in many cases of cancer are not due to degeneration products within the cells, but are due to something living, and the theory of coccidia is giving way to that of blastomyces.

Results at Buffalo.—We have tried cultivations of every possible kind in the State Laboratory for the Investigation of Cancer. Altogether 1200 cultures have been made on 60 different culture media. The result has been most variable. Only once did we find a yeast in pure culture. Only once was inoculation performed successfully. Since a recent visit to Europe we have taken advantage of the technic employed by San Felice in his recent observations. We now use aseptic material from dried lymph nodes for our inoculations. The work has been done only within this last two months, yet three times death has occurred within three weeks after inoculation. In certain of the cases we have found Russell's bodies present in the nodules which occurred in consequence of the inoculation.

BOOKS RECEIVED.

The MEDICAL NEWS *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* MEDICAL NEWS *will shortly appear.*

GENERAL AND LOCAL ANESTHESIA. By Dr. Aimè Paul Heineck. Demy. 8vo., 124 pages. G. P. Engelhard & Co., Chicago.

PROCEEDINGS OF THE AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION, at the Fifty-fourth Annual Meeting, held in St. Louis, May 10-13, 1898.

A PRACTICAL TREATISE ON DISEASES OF THE SKIN. For the Use of Students and Practitioners. By Drs. James Nevins Hyde and Franklin Hugh Montgomery. 8vo., 864 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York. $4.50.

RECENT METHODS IN CARDIAC THERAPEUTICS BY BATHS AND EXERCISES.[1]

BY THOMAS E. SATTERTHWAITE, M.D.
OF NEW YORK;
CONSULTING PHYSICIAN TO THE POST-GRADUATE, ORTHOPEDIC AND BABIES' HOSPITALS.

THIS paper will be devoted to the methods employed for the past two years in this country. So far as I know there has been no material change in the methods used at Nauheim.

I will first speak of exercises and their adjuvants because I usually begin my treatment with them, and because they have a somewhat wider application in cardiac therapeutics than the carbonated baths. Sometimes, in fact, I have given no baths at all, yet have had good results; for it may be remembered that exercises alone will generally accomplish the same results although more slowly and less agreeably than when the two are used in conjunction.

I do not propose to give a recital of well-known details. On two occasions in this hall I have demonstrated my particular methods of giving resistant exercises; while the plan of the baths has been presented to the profession so many times that practitioners have been well-informed as to the way they are administered. However, it will serve the purpose of this paper at this point to make a brief statement about the exercises. They are chiefly voluntary, and consist in flexion, extension, adduction, abduction and rotation of the limbs, neck and trunk by the patient while the operator opposes graduated resistance. Between each single movement, more rarely between groups of movements, there is an intermission. This method, thus described, is known as the Schott System. It consists, therefore, of intermittent, voluntary movements on the part of the patient, resisted by the operator. The ordinary Swedish movements, as they are commonly understood here, are voluntary and unresisted and more or less continuous. They need no operator. But I use also a number of passive movements which I have found of such great value that I never omit them from any course. I have called them respiratory and have described them at length in a paper read before the County Medical Society, February 28, 1891[1]. The two most important are described as follows, the first one being adapted for bed-patients, the second for ambulants. In the first one the patient lies on the back on a couch, with the head and shoulders elevated slightly; the operator standing at the side or back passes his arms under the armpits, raising the trunk slowly as far as possible without actually lifting the patient from the couch. Then the trunk is allowed to return to its former position. It will be noted that this exercise is not to be resisted by the patient. I therefore call it a *passive* movement. It is specially adapted for obese patients, or cases of cardiac dropsy. Each respiratory movement is in the direction of artificial respiration, and should be repeated from one to five times a minute on an average. The other respiratory movement, which I have also described, is designed for patients with a fair degree of strength. The patient sits on a stool while the operator, standing on another stool behind him, passes his hands over the patient's shoulders, grasping him by the axillæ; the patient's body is then lifted upward as far as possible without the patient absolutely leaving the stool. The potency of this operation is now increased by the operator drawing the patient's shoulder over backward as he does it by pressing his knee slightly against the middle of the patient's back, while he draws him over backward. After an intermission the trunk is permitted to settle slowly down into the original sitting position. Of course, the operator needs physical strength for this movement; sometimes in heavy people two operators are required. There are several other respiratory exercises that I have elsewhere described.

Resistant exercises, and in fact all exercises, are less effective if used consecutively. They are best interspersed in a way to give some variety between passive movements, massage, percussion or perhaps vibration. A good scheme of a course is as follows: (1) A respiratory movement, such as has been described (Nos. 33 or 34 of my published series[1]). (2) Elbow flexion and extension (Nos. 3 and 4 of my series). (3) Foot flexion and extension (Nos. 21 and 22 of my series). (4) Abdominal massage. (5) Flexion of leg on thigh (Nos. 35 and 36). (6) Massage of arm and forearm. (7) Arm circumduction (Nos. 7 and 8 of my series). (8) Flexion of knee (Nos. 37 and 38 of my series). (9) Leg massage. (10) Percussion of back, manually or by vibrator (Nissen), with massage.

The séance should at first be short, not over fifteen minutes, especially with delicate people; and in any case it should not last more than an hour. As the course progresses, the number of exercises should gradually increase, more resistance be employed, but intermissions are always to be maintained. Sometimes, however, the patient can not bear any increase in the number of movements,

[1] See Post-Graduate, June, 1898.

and little force can be used. In cardiac cases of a neurotic type, brilliant results are often obtained by pushing the force of the movements to the limit of the patient's tolerance; but each case, of course, requires a somewhat different series of exercises, and herein lies an opportunity for skill and experience.

In addition to the active and passive movements I always insist that the patient walk more or less daily in the open air when it is practicable, or, if he cannot leave the house, in his apartments, which should be well ventilated while he takes his walk. Distances in any case should be gradually increased. Hurried movements, however, must never be permitted. Stairs should be ascended slowly; heavy weights should not be lifted and the patient must be warned that any physical strain may be followed by most dangerous results. But mental strain should also be avoided as far as possible. These two forms of strain, together with overeating, form the most frequent causes of death in chronic heart-disease. Let the patient avoid them, pursue the modern method of treating failing compensation, when it occurs, and he may live to a good old age.

It is a mistaken idea that a patient should always be kept in the dark about his heart trouble. In the vast majority of cases he should be told plainly what his condition is, particularly if the disease is organic, in order that he may take pains to guard against heart failure. I feel convinced that by pursuing this plan, many valuable lives may be indefinitely prolonged.

At this point I wish to say that a patient should be prepared for a course of treatment much as he would be prepared for a major physical operation. During the preliminary treatment many important data will be obtained and it may be possible to remove suspicious quantities of albumin, sugar or even granular casts, so that the baths can be undertaken in safety, which otherwise would be a source of constant danger. Slight albuminuria, a small amount of glycosuria, and moderate cardiac dropsy, do not absolutely contraindicate a course of baths.

If the patient can take a regular six weeks' course, which is advisable in all cases, I do not at first carbonate the bath, but during the second week I employ a quarter of one per cent. of the gas. From the beginning of the third week to the end of the sixth week, the strength of the baths in salines, carbonic acid, and finally chloride of calcium should be gradually increased. The immersion should not last less than four minutes, nor more than fifteen. In a delicate persons the duration should be short. As a rule, all patients are to begin with a bath at 98° F. But some effort should be made to reduce the temperature gradually, although never more than a degree a day. I am unable to use a bath at as low a temperature as 85° F., which is the point to which in Germany they attempt to reduce the temperature. Such a low degree of temperature would not be well borne in this country. If the patient can endure a bath at 89° F., it must be regarded as something unusual. Usually it does not fall below 92° F. Sometimes the temperature cannot be reduced at all, and a bath should never be given in which the patient on immersion has a sensation of chilliness.

Baths and exercises are omitted in cardiac cases at intervals of three, four and five days. So that in a course of forty-two days there should be nine intermissions. These intervals have various uses; they give a physician an opportunity to make a special examination of the patient and his environment; but more than this they seem to have a salutary effect for reasons that are not clear. Certainly these intermittent baths are more effective than consecutive baths. While a course ordinarily lasts six weeks, I sometimes give a modified course, lasting several months; in fact, more or less throughout the entire year. (By this method we have an advantage over the Nauheim system. We give ours continuously throughout the year; in Nauheim the baths can only be given in summer-time.) Modified courses are suited for locomotor ataxia, probably for various forms of myelitis, for neurotic forms of heart diseases, neurasthenia, melancholia, insomnia, the drug habits and chronic rheumatism.

I do not propose to discuss here the older methods of carbonated baths by the use of crude muriatic acid or liquid carbonic acid gas. I have used both, the latter extensively. The one is too dangerous, the other is unsatisfactory for reasons known to chemists or pharmacists. There is always a danger from the bursting of the drum or cylinder. There have been a number of accidents from this cause. More than this, it is practically impossible to accurately charge the bath with the desired amount of carbonic acid, for carbonic acid gas is absorbed by water in proportions varying with the temperature of the air and the water. Even if every precaution is used, a great deal of gas is lost. In fact, I do not believe that liquid carbonic acid in any form will ever be employed to any extent in making carbonated baths. Fortunately, we have no use for either of these methods. Mr. H. A. Cassebeer of this city adopted some time ago the plan of Sandow of Germany, and made solid discs of the bisulphate of soda as a substitute for the crude muriatic acid, so that now with the aid of the commercial bicarbonate of soda any one can carbonate a bath safely, quickly and inexpensively, obtaining the amount of carbonic acid gas that may be desirable, with a reasonable degree of accuracy. The Triton Company of this city, following Mr. Cassebeer, supplies similar discs and soda all put up in neat boxes. So that now all the materials for carbonating a bath can be obtained from any druggist in the country. In some respects this artificial bath is superior to the original. It is entirely free from iron, earthy and other extraneous matters found in the Nauheim waters, which have no curative value, but the amount of carbonic acid as artificially prepared in the bath, and the amount of salt and chloride of calcium

can be made to correspond practically with the same ingredients as found in the natural Nauheim waters. As the course nears the end I use the imported Nauheim salts, known here as the concentrated Nauheim Brine Salts. They are a convenient vehicle for the chloride of calcium, of which they contain about 75 per cent. I feel confident that they add to the efficacy of the bath.

These salts are the uncrystalized residue of the salt works at Nauheim, and are produced by boiling down and evaporating the mother liquor after the commercial salts have been extracted. For the brine I use an American bathing salt as a rule, although in delicate cases I sometimes prefer sea salt in order to secure the bromine and iodine that they contain. For the past year I have been using the purified Genesee bathing salt obtained from the mines in this State. This bathing salt is of very superior quality. I doubt if it has any superior.

The method of preparing a bath is as follows: Fill the bath-tub, whether porcelain, enameled iron, wooden or painted, or merely metal lined, with fifty gallons of water, at 110° F.; then add the desired amount of ingredients as shown by the special directions which follow. First, place the tablets or discs of the acid sulphate, more or less broken or pulverized, at various points on the bottom of the tub. If the tub is of porcelain, enameled iron or wood, they may be placed immediately on the bottom. If the tub is of unpainted metal or painted, wrap each of the pulverized discs in a little bit of tin foil or rubber sheeting; then add the bicarbonate of soda. Evolution of gas takes place in three to ten minutes. The patient should enter the bath at 98° F. and remain in it during the prescribed period of time. The salt should be introduced either before or after the acid sulphate. When the gas is evolved it will be seen to attach itself to the trunk and limbs under the form of minute bubbles. My scheme for an ordinary six weeks' course is at the present time, as follows:

First week: Half a per cent. warm sea-bath (2 pounds bathing salt to 50 gallons of water), temperature 98° F., duration four minutes. Intermission on third day. Second week: Three-fourths per cent. warm bath (3 pounds salt to 50 gallons). Temperature 97° F., six minutes. Intermission on fourth day. One-fourth per cent. carbonic acid gas (2 discs to a package). Third week: One per cent. warm salt bath (4 pounds to 50 gallons). Temperature 96° F. Carbonic acid gas ½ per cent. (4 discs to two packages), four minutes. Intermission on fourth day. Fourth week: One one-fourth per cent. bath (5 pounds salt to 50 gallons). Temperature 95° F. Nauheim concentrated brine salts,[1] 8 ounces, ten minutes, carbonic acid gas three-fourths per cent. (3 packages to 6 discs). Intermission on fourth day. Fifth week: One-half per cent. bath salt (7 pounds to 50 gallons). Temperature 94° F. Concentrated brine salts, 10 ounces. Twelve minutes. Carbonic acid salts three-fourths per cent. Intermission on fifth day. Sixth week: Two per cent. salt bath (10 pounds to 50 gallons), temperature 93° F. Concentrated brine salts, 12 ounces. Carbonic acid gas one per cent. (4 packages in 8 discs). Fourteen minutes. Intermission every fifth day.

In sthenic cases I begin at once with the carbonated bath; with feeble persons I am apt to omit the last two baths of the series. (Nos. 5 and 6.) In neurotic cases it is not advisable to use the concentrated salts, and the patient may oscillate between the two weaker carbonated baths. By this method the baths can be kept up more or less continuously for several months. Baths given with too much carbonic acid gas, too often, or of too long duration, excite the nerves, diminish the appetite and reduce the strength. Accidents seldom happen when the patient adheres to the rules above laid down, but, I am sorry to say, these baths are now given by persons with limited experience, without the supervision of a physician. This matter cannot be too strongly discountenanced, and, yet, I will go further and say that patients are sent from abroad to be treated by these unqualified persons without the direction of a physician on this side of the water. Of course it cannot be wondered at if failure results in such cases; but more than this, serious accidents are likely to happen. Cases of chronic heart-disease are always in a more or less precarious condition, and the management of them should be exclusively in the hands of licensed practitioners. Resistant exercises and massage act much as do the baths, as I have already said, but are not so prompt or certain in their action. Both of them improve the superficial and deep circulation, the former by mechanical means, the blood being invited to the limbs and extremities thus obviating congestion of internal organs. In so doing a dilated heart is relieved of its internal pressure and given an opportunity to contract. It must be remembered that the muscles constitute from one-third to one-twelfth the weight of the body, and during contraction their veins and lymphatics are emptied, thus diminishing peripheral resistance, so that the arteries, which are not contracted by the exercises, are free to carry the blood to the extremities. That the heart actually contracts in many cases seems now to have been abundantly shown by numerous experimenters. Indeed, it seems to have been proved with considerable accuracy by the skiagraphs of Schott.[1] As to a comparison between manual and mechanical methods, I desire to speak with caution. It is true that the mechanical method (the Zander, for example) assures precision in its adaptation to a locality and in the regulation method of force; but I doubt if any mechanical method is as well adapted to varying individual needs

[1] Concentrated lime salts are furnished by H. A. Cassebeer, the druggist of this city, at 50 cents per pound; he also furnishes the other ingredients for the bath.

[1] Deutsche med. Woch., April 1, 1897.

as the hands of an operator backed by skill and intelligence. People sometimes say they do not understand how these grand results are obtained, but the explanation is not difficult to make. While the initial exercises are mild and do not tire the patient they can be made very forcible, and, indeed, produce great weariness; in fact, they are more effective than any form of deep massage, on the other hand, the effect of the baths is due to the warm brine, the gas and the chloride of calcium; each has its special value. The warm bath alone, when it reddens the skin and causes congestion of the capillaries, gives some relief to a dilated heart. Carbonic acid gas is a combined stimulant and anesthetic; while it numbs the skin it also stimulates it. By acting as a local agent this latter effect is intensified by the chloride of calcium. The bath improves the pulse by making it stronger and less frequent. In tachycardia it will reduce the pulse, and in bradycardia will increase it. In one of my cases of tachycardia an average pulse of 125 before the bath fell to an average of 111 after nine successive baths; an average fall of 14 points. In the same patient, with an average of 123 before the exercises, there was an average fall to 110 afterwards, showing, if anything, that the effect of the bath was a little more marked than the exercises. Ordinarily there was a fall of from 3 to 5 points after the bath, but not quite so many after exercising. These statements go to show, as stated, that the baths are more effective than the exercises. On the other hand in a case of bradycardia, I have known an average pulse of 60 to rise to a point between 70 and 74 after a bath. Among other effects of the bath there is increased renal secretion, with some disappearance of exudations in internal parts.

While, however, baths and exercises have gained their principal reputation by employment in the treatment of chronic valvular disease, where compensation has been broken and so-called heart tonics have failed to make the heart respond, carbonated brine baths have also been used in rheumatism and gout, chlorosis, typhoid fever, and in some functional and organic nervous diseases, such as locomotor ataxia, matters to which I have already alluded. I should fail, however, to describe this method accurately if I omitted stating that there should be a definite system of diet, and that the gastro-intestinal tract should be carefully attended to.

But contraindications are important. Baths should not be used in Bright's disease, where the parenchyma of the kidney is seriously involved. In Graves' disease, with cardiac dilatation, baths are of doubtful value. Many cases of arteriosclerosis are not benefited. On the other hand, baths and exercises may be used with advantage in arteriosclerosis sometimes, as, for example, when a well-marked syphilitic history is recognized and treated. In general cardiac dropsy, if extensive, and advanced stages of phthisis there is not much hope for improvement by either baths or exercises. The baths are applicable in my experience to about 80 per cent. of cases of chronic heart-disease with broken compensation. In the remaining 20 per cent. exercises combined with massage may be of considerable help. Although in the majority of cases I use no so-called heart tonics during treatment, one must at all times be prepared to treat the heart in this way and if our treatment by baths and exercises has for any reason to be suspended, we may be compelled to use them. Digitalis still stands at the head as a direct heart stimulant, nitroglycerin is a good second, and strychnine often a good third. In cardiac dropsy digitalis is easily at the head for its diuretic effect; I use it in the form of digitaline (Merck) in a hundredth of a grain doses given every three to eight hours. Nitroglycerin in doses of $^1/_{150}$ to $^1/_{50}$ of a grain I have given as often as every hour. Strychnine in doses of $^1/_{60}$ to $^1/_{30}$ of a grain I give every four hours. Calomel in small doses I usually give two or three times a week; in bad cases I give it daily. As a rule I use Carlsbad salts as a purgative. The bowels must always be kept in a relaxed condition. For sudden attacks of dyspnea I give capsules containing each $^1/_{100}$ of a grain of nitroglycerin, ¼ of a grain of amyl nitrite and menthol $^1/_{50}$ of a grain, with the oleoresin of capsicum $^1/_{100}$ of a grain. These ingredients are suspended in ten minims of castor oil. This combination is very effective in attacks of angina pectoris, whether true or false. Relief is usually given in less than a minute, often in a few seconds. As a diuretic and heart stimulant I have also had good results, though often temporary, from the sulphate of sparteine in doses of $^1/_{20}$ to $^1/_{10}$ of a grain. The monobromate of camphor is used constantly in some neurotic cases. In cardiac dropsy, however, we should always aim first to secure free diaphoresis and for this purpose I use the muriate of pilocarpine (Merck), giving sometimes as much as one grain a day in conjunction with digitalis, nitroglycerin and stimulants. In fact, I have given 1⅗ grains of this drug in a day, because it required this amount to secure diaphoresis. I have never had any ill effects from it, but always have had an experienced nurse to watch its effects. The comparatively small number of cases seen that are beyond the treatment by baths and exercises, and where it is only a question of prolonging life a few months at best.

I do not wish to be understood, therefore, as urging the use of the so-called heart tonics or stimulants; they are the last remedies to be used. I want it fully understood that in broken compensation the effort should be rather to remove obstacles to the circulation than to compel a weak heart to forceful action by the remedies just mentioned, and it is very remarkable how by giving close attention to these simple methods a weak heart will gradually become stronger.

A good deal of interest has lately centered about the comparative methods of skiagraphy, fluoroscopy and percussion, in outlining the heart. It may be remembered that on March 6, 1897, in

this Academy, I demonstrated a new way to indicate the location, size and movements of the heart, by means of X-ray shadows. At that meeting I was able to mark out the limits of the heart on the fluorescent screen. I called this method *fluorography*, and my confrères, Drs. Porter, Burt and Wilcox, who had examined the patient whom I presented and marked out the heart, were unanimous in stating that by my method there was wonderful correspondence between the two methods. In a recent article by Dr. Williams[1] of Boston I find that his investigations have in a measure confirmed those that I made; if I understand his figures, in 65 out of 71 men he found that the difference between the results of percussion and fluoroscopy was less than three-twentieths of an inch. In 33 out of 38 women, the difference was also less than three-twentieths of an inch. Now this lack of correspondence may appear large, but in reality it does not prove much. For leaving out of question the inevitable inaccuracy of fluoroscopy, we have to deal in these cases often with a wide movement of the heart, as shown by its apex, for example. To be precise in the four cases of dislocated heart from spinal curvature, published by me (*N. Y. Med. Jour.*, Sept. 30, 1899), there was a recession toward the normal of from 5⅛ to 2½ inches, or an average of 1½ in round numbers. Evidently then an error, if there should be one, of $^{3}/_{20}$ of an inch in the percussion outline would be of comparatively little importance in these particular cases. It seems to me, therefore, that fluorography, or fluoroscopy, is gradually coming to the front and this view is sustained by the opinion of Stubbert, Abrams, Tracy and Roberts.[2] Skiagraphs are, as Tracy[3] has pointed out, notoriously fallacious, as he shows in a quotation from Dr. Keen of Philadelphia, who, judging from a skiagraph that a bullet lay outside the head of the tibia, cut down upon it, only to find the entire ball within the bone. Of course, skiagraphs have their merits and in this connection it may be well to note the investigations of Schott. Desirous of showing by the X-ray that the heart if dilated will contract under his treatment, he placed a patient with artificially dilated heart[4] on a table, resting on a large piece of paper, the outline of the body indicated by a line carried around the body just as a shoemaker outlines the foot in preparing to make a pair of shoes. Then with the focus tube firmly fixed in a given position beneath the table, and a sensitive plate above the patient and in a fixed position, a skiagraph was taken of the heart. After an interval of rest the patient was skiagraphed on the same table in exactly the same position, with the apparatus also unchanged in position, and the skiagraph showed a positive diminution in the size of the heart. Of course in this case there was the usual distortion, the heart being magnified by the divergent rays from the focus tube, but inasmuch as the patient, the tube, and the plate occupied precisely the same positions in each case a good idea of the contraction of the heart was obtained by comparison of the two pictures. Of course neither fluoroscopy nor skiagraphy give as yet accurate pictures of internal organs, but the errors may not be, in my opinion, insuperable. In a paper read in this building March 16, 1897, I said, speaking of fluorography, that I was not prepared to state that it would supersede percussion for mapping out the heart, but that I could conceive that the size, position and measurements of the heart might be determined by fluorography without either percussion or auscultation. This position I maintain at present, but I see no need of abandoning percussion in favor of these two other methods; and yet I believe that the time is not far off when some simpler plan will be devised for throwing a correct silhouette of the heart on the fluorescent screen. But for the present I find that auscultation in combination with percussion is the best all-round method of mapping out the heart for clinical work.

MILK INSPECTION BY THE NEW YORK BOARD OF HEALTH.

By HERMAN BETZ, M.D., Ph.G.,
OF NEW YORK.

The object of the present communication is to present a brief statement of the routine of milk inspection as carried on by the Department of Health in New York City.

The milk-inspector is appointed from the head of the list after passing a successful Civil Service examination, from which, until recently, all except physicians, pharmacists and chemists were barred. At an appointment of five some time ago four had above 90 points each to their credit after a most severe examination. The knowledge that such men bring to bear upon their work cannot fail to give satisfactory results. The use and handling of apparatus and scientific instruments is no secret to them, and they are, from the start, able to do satisfactory work. Their greatest strength is shown, however, in trials of milk cases, where shrewd lawyers are frequently employed on the other side, and where any one but a man with a scientific training would fail.

The milk-inspector is on duty, technically, all the time; he may be called upon at any hour, day or night, Sundays as well as on week-days, for it is obvious that a dishonestly inclined milk-dealer, who behaves himself during the week, should not be left under the impression that he can do as he pleases on Sunday. I wish to say right here, however, that there are not any more dishonest men engaged in the milk business than in any other business, possibly less. The relation existing between milk-dealer and milk-inspector is much more cordial than it would be supposed; the Department of Health is always fair, and the milk-dealer is absolutely sure of that fact, for he

very seldom contests nowadays the analysis or the result of analysis of a sample of milk.

There are now employed by the Department of Health ten milk-inspectors in the borough of Manhattan. I am using the borough of Manhattan for an illustration, although the same system prevails in all of the boroughs. The borough of Manhattan is divided into nine milk districts, which makes it possible to have the entire borough constantly covered; the tenth inspector is required to take the place of any one who should be taken from his work by sickness or other reasons; this inspector also makes sanitary inspection in places where milk is sold, when he is not otherwise engaged. The nine districts are so arranged that an equal number, or nearly so, of milk places come within the boundaries of each, which means about 650 in each district on the east side and 700 on the west side.

The milk-inspector is obliged to spend from 9 A.M. to 4 P.M. in actual inspections, after which he writes out a daily report of every place visited by him during the day, giving the time by hour and minute, the name and address of the milk-dealer, the permit number under which the dealer does business, and the temperature and lactometer standing of the milk so examined.

The report must be in the Chief Inspector's hands by 9 A.M. each day. On Monday morning a weekly report also is handed in giving the number of inspections made each day, as well as the total number for the week, his attendance at court, and arrests and fines also must be carefully recorded.

The following instruments and utensils are supplied to the milk-inspector, which he carries about with him in a suitable satchel:

A lactometer; a thermometer (dairy style); a cylinder of tin in which to float the lactometer; lead seals and wire for sealing sample-bottles of milk; one seal punch with two dies, one impressing the lead with "Health Department, Manhattan," the other the inspector's letter which has been given him for his identification as A, B, C or D, etc.; a writing diamond, to mark sample-bottles; six ounce-bottles with two holes in neck opposite each other, through which the wire is passed holding the cork immovable, unless the seal and wire are disturbed, for dealer's sample; four ounce-bottles for samples of milk for analysis at laboratory; one box of labels, gummed on back, for marking above sample with inspection number, sample number and lactometer standing at 60° F.; a book of 50 labels to mark dealer's sample, as also a stub corresponding with same, which is afterward attached to the analysis report; a book in which is reported the year, month, day, hour and minute when inspection is made, the number of inspection, the name and address of the dealer, number of years in business, number of quarts sold per day, number of permit under which business is done, name and address of the wholesale milk-dealer from whom he receives his supply, the gross and net lactometer standing and the temperature of the milk examined, also physical properties, odor, taste and appearance, the name of person present when examination is made, whether proprietor of store or representative, and, lastly, the mark which is found on top of cover of milk-can.

The mode of inspection is as follows: When an inspector enters a place where milk is sold he announces this fact to the proprietor of the place or his representative. After he has satisfied himself that the milk is properly cooled and utensils for measuring are clean, he stirs the milk thoroughly, fills his tin cylinder within two inches of the rim, leaving room for displacement by lactometer; the lactometer is then carefully lowered into the milk care being taken that the stem is dry. While the lactometer is allowed to come to rest, the thermometer is used to carefully note the temperature, this and the lactometer's reading are carefully entered in the inspection-book and for every three degrees of temperature below 60° F. one degree is deducted on the lactometer, or added if the temperature is above 60° F. Should the milk present a good appearance and stand somewhere between 108 and 112° on the lactometer at 60° F., the milk-inspector will pronounce the milk good, but if the milk should stand below 108 or above 112° net on the lactometer, and not be of good physical appearance, he will consider the milk suspicious and proceed to take a sample from same, as follows: The proprietor of the milk-store, or his representative, will be asked if the milk is for sale. Should he state that it is for sale the inspector will ask him to stir the milk well himself and again test with thermometer and lactometer, calling the proprietor's or his representative's attention to the various points; should it be possible to procure another witness to the proceedings it is desirable to do so. The six-ounce bottle mentioned above is then filled up within a short space below the neck to allow sufficient room for expansion and the cork forced in well below the two perforations mentioned above. The wire is then passed through the orifice in the bottle, forced through the cork and out through the opposite perforation in the bottle, and then wound twice around the neck of the bottle and over the groove in the lead-seal, which is then forced down over the wire by the punch until it presents a quite flat appearance with the imprint on both sides, as described above, and from which the wire cannot be removed without destroying the seal and imprint. The sample is then labeled with the part of page which corresponds with the stub described, and which is gummed on the reverse side. Both stub and label are counterparts of each other bearing number of inspection, date, name and address of dealer, reason for taking sample, inspector's name and the number of sample. This bottle is then sealed and labeled as described above, and handed to the dealer or his representative, to be held by him, or to be given to a chemist for analysis if he so chooses. This is now done but seldom, dealers, both wholesale and retail, are so convinced of the absolute correctness with which analyses are made at the Depart-

ment laboratory that they usually instruct their lawyers to concede the analysis. The four- ounce square bottle is now filled with some of the same milk, and to this is attached a square stick-label bearing inspection and sample number as well as inspector's letter described before. The inspector now proceeds to the laboratory of the Department. When he arrives there he will hand the sample bottle to the chemist or assistant chemist in charge, who will sign a receipt for same on a ticket made out by the milk-inspector, on which are again given the milk-dealer's permit number, year, month, day, hour and minute of inspection, but the space for the milk-dealer's name and address is left blank for the time being; the ticket also gives the wholesale dealer's name and address from whom the retailer receives his supply, and the number of specimens of milk examined, their standing both by lactometer, thermometer, and net, also physical appearance. As this ticket is used by the inspector on the stand in trials to refresh his memory, it is made out with great care, and gives in addition to the above facts the recorded numbers of the instruments used, for it has happened in some important trials that the correctness of the instruments has been questioned. For this reason as soon as a lot of lactometers or thermometers is received from the manufacturer they are carefully tested in our laboratory; if they come up to the standard they are accepted, numbered and the record of the same is kept at the Chief Inspector's office; if they are found to vary perceptibly they are rejected. The same ticket also records the fact whether the can from which the sample has been taken was wired, the amount of milk the can contained, the fact that the milk had been stirred by the proprietor or his representative, the marks found on shoulder and cover of can, the location of the can in the store or place in which the milk was sold; whether the can contained a dipper, whether this inspection was made on the regular routine inspection or upon a complaint from a citizen, the total number of cans examined at that particular inspection, the name of the witness present at the time of inspection, and also a space in which to record the date on which the warrant was obtained. In case of prosecution the number of the City Magistrate's Court, the date, when, and the amount of bail obtained, and, finally, the Court in which the case was tried and the amount of fine paid or the disposition of the case, whether dismissed altogether or sentence suspended. All this is recorded on the front of the ticket; on the reverse side is given, first, the receipt of the chemist for the sample, then the analysis as follows:

Water, per cent.; total solids, per cent.; fat, per cent.; solids not fat, per cent.; per cent. low in solids; per cent. low in fat; borax, present or absent; salicylic acid, present or absent; formaldehyde, present or absent; reaction, acid or alkaline.

The name of the assistant chemist who has performed the analysis is also given and is countersigned by the chemist. This completes the ticket, as far as the inspector can complete it at that particular stage. The ticket with the stub is then handed to the clerk in charge of milk analyses in the Chief Inspector's office, which ends the milk inspector's duty for the present as far as this particular sample is concerned. The clerk in charge of milk analyses, just mentioned, enters up all the facts given in a book in which spaces are provided for all the facts given above; the ticket is then placed in an envelope with others which may come in on the same day, giving the exact time when received from the inspectors, when forwarded to the laboratory and when received back again. After forty-eight hours the analysis is finished and the chemist will then fill up the space provided for percentages of water, total solids, fat, etc., and whether the milk has been found unadulterated or short in total solids or fat, giving the exact amount. The ticket is then immediately returned by the chemist to the clerk in charge of milk analysis, who enters up all the various facts found by the chemist and then fills in the name and address of dealer from the stub. The ticket is now ready for the Chief Inspector who will determine by the percentage of fat or total solids shortage whether an arrest is to be made or not. The rule followed at present is that the dealer is to have the benefit of the doubt up to four per cent. of solids and nine per cent. of fat, but if the shortage is five per cent. or over in total solids, or a shortage of ten per cent. or over of fat, prosecution is at once to be started; such tickets are, therefore, signed by the Chief Inspector and stamped "Arrest" or "Do not arrest," and after the ticket has been countersigned by the Sanitary Superintendent the clerk in charge of milk analyses will notify the milk-inspector that a ticket is awaiting him at the office for arrest. The milk-inspector upon receipt of the ticket prepares an affidavit of the facts in the case and asks for a warrant for the milk-dealer's arrest in the City Magistrate's Court in whose districts the violation has taken place. This warrant is usually granted and a day of hearing is set, the warrant is served by a court officer in as inoffensive a manner as possible; that is, by simply notifying the dealer that his presence is required in the court to which the officer is attached, for violation of the Sanitary Code by selling adulterated milk, and that probably it would be best for the dealer to bring with him a bondsman. At the day and hour set for the hearing the milk-inspector states his case and requests that the defendant be held under bond for trial in Special Sessions. The City Magistrate usually names a bail amount of $100 which the milk-dealer furnishes through a friend, or in many cases the wholesale dealer who has furnished the milk furnishes the bail. If the defendant is represented by counsel, the counsel frequently requests a hearing, but the outcome is usually the same. After a lapse of but a short time the case is set down for trial at Special Sessions, where the judges without exception have taken great in-

terest in these milk cases; some of them even have taken the trouble to inform themselves of the various stages of analysis, being present during an actual analysis at the laboratory. They are well posted in relation to the provisions of the Sanitary Code and the agricultural laws of this State relating to milk and dairy matters, total solids, fat, solids not fat, the name of antiseptics and like terms and their meanings which are usually so puzzling to outsiders, and even lawyers who try these cases understand them as well as any chemist. It is directly due to this intimate knowledge of terms, facts and matters connected with the scientific part of milk analysis, and the recognition of the earnest efforts of the Health Department to improve the milk supply of the City of New York, that it has been able to carry on milk-inspection with satisfactory results; for what would all this work amount to did not the courts so ably and conscientiously carry out their part.

Tickets which have been used for prosecution are filed in a record cabinet in alphabetic order, separately from those where no prosecution was deemed necessary, or where upon analysis of the sample it was found that the milk was unadulterated.

Since 1896 the Department of Health has required every dealer in milk to take out a permit, in order to better regulate the care of milk and enforce the Sanitary Code. A prospective dealer applies at the Department office in person for a permit by filling out an application giving his name and address, the kind of business he is engaged in, the amount of milk—approximately—he expects to sell per day, the dealer from whom he is to derive his supply, the hour of day the delivery takes place and the can-marks he finds on the cans, also whether he intends to handle any condensed milk in bulk, and, furthermore, where he intends to keep the milk in storage while selling, if in an ice-box or in tubs, whether such receptacles are connected with the sewer or not. This application he signs and is then given at once a temporary permit, which he may show to the inspector when he makes his customary round; for it is one of the milk-inspector's duties to at once report any places where milk is sold without a permit. The temporary permit, therefore, is required to prevent confusion and unnecessary reporting. After the application mentioned above is placed on file, the name and address is given to the milk-inspector who is making his sanitary inspection as mentioned at the beginning of this article. Should this inspector find that the place is in a sanitary condition he so reports at the office at once, and the application goes forward to the Board, and will very probably be granted at the next Board meeting. The inspector, however, may find that the place inspected is not in proper condition, and this may be due to various causes; the most frequent one is that there is but one room, without any partition, and the proprietor of the place, or his help, sleep in the rear part, or the rear part is used for other domestic purposes; or the place is kept in an unclean condition, or the receptacles in which the milk is kept are not proper; in all such cases the inspector will give directions as to what necessary changes have to be made to put the place in proper shape. A reasonable length of time is given to make the change, the regular permit in the mean time is withheld; if, however, at the next inspection nothing has been done to bring about the sanitary condition necessary, the permit will be refused and the dealer compelled to give up the sale of milk. After the granting of the permit the dealer calls for it, issued to him without charge but it is revocable at the pleasure of the Board of Health, and must be hung up in a conspicuous place; for that purpose the permit is printed on heavy cardboard. This permit need not be renewed, but should a dealer be twice convicted of the sale of adulterated milk the permit will be taken from him, revoked, and the Department will never allow him to sell milk again. For this purpose a record is kept at the Department of all dealers and their convictions, on cards especially adapted for that purpose.

The wholesale dealer is obliged to furnish more direct information if he received his milk from the farms; he must give the farmer's name and address, the station from which the milk is shipped, and the railroad carrying same; also the time of arrival of the milk at the terminal station and the number of hours the milk is in transit. In addition to this he must furnish the name of the breed of cows the farmer keeps, the number of cows and the water-supply for the cows and the water used for cleaning cans and other utensils. If a creamery supplies the milk a special blank is filled out giving the name of every farmer contributing milk to this particular creamery and all other information required, as in the case of the shipment by the farms direct. The permits issued to the wholesale dealer will be as many as the wagons he employs; he is also obliged to give the name of the driver employed and the driver's address. These permits are to be carried by the driver, and the number of same must be painted on each side of the wagon in some contrasting color to that of the wagon and in letters one-half inch wide and two inches long. There are at present 7000 store-permits and 1800 wagon-permits in existence.

An arrangement exists between the Department of Health of New York City and the Boards of Health of the various States from which milk is shipped to New York to immediately notify this Department if any contagious or infectious diseases have broken out at any town, village or settlement within their jurisdiction from which milk is shipped, this information to be given by telegraph, upon receipt of which the Department takes steps to immediately quarantine the milk from that particular place. In order to do this effectively a record is kept at the Department of the various railroads and the districts they tap, the party who receives milk from such places in this city and the amounts received. This record has been on several occasions of the greatest ser-

vice in preventing the spread of disease. The compilation of this record is the work of one of the milk-inspectors now employed by the Department, and required rare tact and ability and unceasing work for nearly six months; not in the day-time, but principally at night and in all kinds of weather, because ordinary information could not be relied upon, but had to be verified by actual count and checking at the various depots, ferries and receiving stations, at the arrival of the milk-trains; but the work was splendidly done and the record is to-day, with occasionaly changes and additions, one of the most highly prized in the possession of the Division of Milk Inspection.

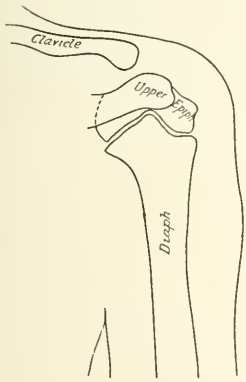
SURGERY OF THE EPIPHYSES.

By CHARLES L. SCUDDER, M.D.,
of Boston;
Surgeon to the Massachusetts General Hospital, out-patient department; assistant in clinical and operative surgery in Harvard University.

Many of the epiphyseal separations are mistaken for fractures in the neighborhood of the epiphyses. The Roentgen ray is revealing with a great degree of accuracy the lesions after traumatism to joints. Along with perfection of diagnosis comes obligation to correct deformity in order to secure greater functional usefulness. This obligation, because of perfection of aseptic technic, necessitates the open incision of many closed fractures and epiphyseal separations. To state all the conditions under which fractures and separations should be operated upon is impossible until more experimental work is done and the results are fairly compared.

Fig. 1.

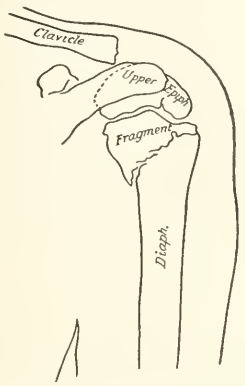


Normal epiphysis of upper end of humerus in a boy aged seven years.

Poland and Bruns, in 1884, each advised operation when the deformity following the injury to the bone could not otherwise be reduced, or could not be held reduced. As in all operations involving joint surfaces, the surgeon should be skilled in aseptic technic and every minute detail of operative surgery should be carried out with the greatest care.

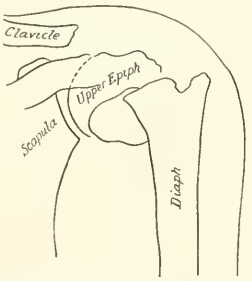
The publication of John Poland's[1] book upon the traumatic separation of the epiphyses, published in 1898, establishes a scientific basis upon which the surgery of the epiphyses may rest. It is a valuable work, not alone for the original investigations made by the author, but for the great mass of scientific material systematically presented. It is exhaustive and extremely suggestive. The development of the epiphyses of the long bones should be carefully studied. The important details in the anatomy of the epiphyses should be constantly in mind during the examination of an injury in the neighborhood of joints.

Fig. 2.



Fracture of diaphysis of humerus close to epiphysis. Epiphysis injured, but not displaced.

Fig. 3.



Fracture of the diaphysis of humerus close to the epiphysis, as in Fig. 2, before attempt at reduction.

The following cases of surgery of the epiphyses are reported:

Case I.—In June, 1899, I saw, in consultation with Dr. Godfrey of Littleton, Mass., a boy four-

[1] Traumatic Separation of the Epiphyses; John Poland, F.R.C.S., London: Smith, Elder & Co., 15 Waterloo Place, 1898.

teen years of age who had fallen from the roof of a shed and sustained the following injuries: Separation of the lower epiphysis of the left humerus, with a dislocation of the diaphysis of the humerus forward through the skin upon the outer side of the upper arm, and a closed fracture of

Fig. 4

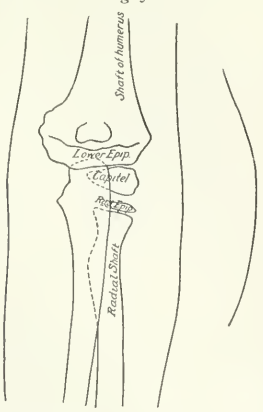
the radius and ulna of the same arm at the junction of the middle and lower thirds. The bone was very thoroughly cleansed by scrubbing with corrosive sublimate, the wound of the soft parts was completely cleansed with the same solution. The wound of the soft parts was enlarged in order to admit of easy access to the seat of

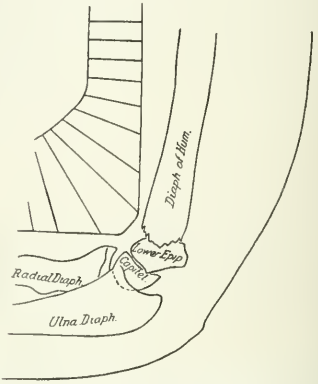
Fig. 5.



Normal elbow. Forearm extended. Note the relations of the epiphyses.

fracture. The joint was found open. A counter-opening was made on the inner side of the arm to allow of more thorough cleansing of the deeper parts of the wound. Small wicks were left in each wound. The arm was put up in a plaster-of-Paris dressing, the forearm semisupinated. Two years and two months after the accident all movements of the forearm and elbow were normal. The carrying angle was lost and the left hand and forearm were smaller than the right. The humerus measured the same upon each side from the acromion to the external condyle.

Fig. 6.



Separation of lower humeral epiphysis. Immediately after reduction. Internal angular splint in position. Arm at right angle.

Case II.—A boy, seven years of age, as a result of a comparatively slight fall, fractured the diaphysis of the humerus close to the epiphyseal line. There was also contusion of the epiphysis itself. The symptoms closely simulated those of separation of the epiphysis. The boy pre-

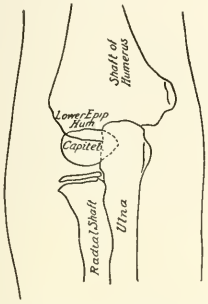
sented a much swollen shoulder, upon the anterior surface of which was a prominence below the normal place for the head of the bone. The head of the bone was felt to be in the glenoid cavity. The upper end of this prominence was continuous with the shaft, was rather smooth, and projected like a shelf upon the anterior part of the shoulder. The prominence moved with the

movements of the humeral shaft. Muffled and cartilaginous crepitus was felt very distinctly upon moving the shaft of the humerus while the head of the bone was held fixed. There was shortening of the left humerus. Measurement was taken from the acromion to the external condyle of the

Fig. 8.

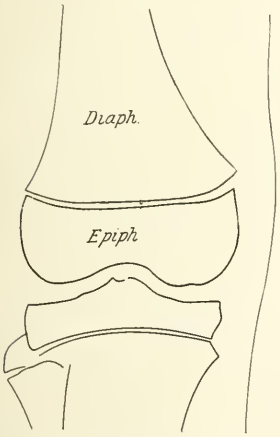


Separation of lower humeral epiphysis. Six months after the accident. Arm in extension. Humerus thickened at line of diaphyso-epiphyseal junction.

humerus. The tracings of skiagrams taken the day of the accident and of those taken six months later are extremely instructive. Functionally the arm is perfectly useful. Extreme abduction is very slightly limited. (See Figs. 1, 2, and 3.)

Case III.—A girl, six years of age, after

Fig. 9.

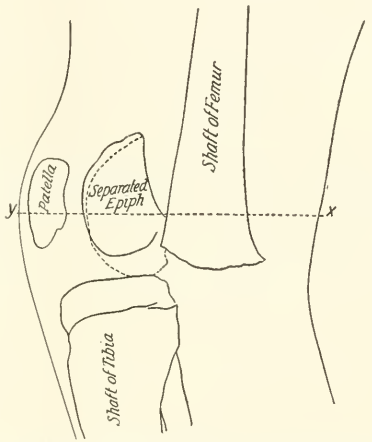


Case IV.—Normal knee of a boy 11 years of age. Epiphyses in anteroposterior view.

slight trauma to the elbow, showed a separation of the lower humeral epiphysis. There was present unusual lateral mobility at the level of the epiphyseal line. The lower end of the diaphysis of the humerus projected slightly forward, the separated epiphysis was displaced with the forearm backward. Muffled crepitus was present. The deformity tended to easy reproduction. Considerable swelling of the elbow existed. There were no complications. The child was etherized and by traction and counter-traction upon the forearm and upper arm respectively the displacement was reduced. Immobilization was secured by an internal right-angled splint. After six months the functional usefulness of the elbow was good and all the movements of the elbow-joint were normal. The tracings of the skiagraph are correct interpretations of the condition present. (See Figs. 5 to 8, inclusive.)

Case IV.—On March 22, 1899, a boy, eleven years of age, entered my clinic at the Massachusetts General Hospital with a swollen and deformed knee. He was said to have caught the leg

Fig. 10.



Case IV.—Separation of the lower femoral epiphysis. Lateral view immediately after the injury. Knee thick- and through the level of the popliteal space. *y*, *x*.

in the spokes of a revolving wagon-wheel. The left knee appeared swollen and the leg was carefully steadied by the boy in order to avoid any jarring. From the anterior superior spine to the internal malleolus there was seven-eighths of an inch shortening upon the left side. This shortening was wholly in the thigh. The whole leg rotated inward, the great toe pointing toward the right. A slight abrasion was noticed over the patella. There was a distinct hollow just above the patella. A great fulness existed in the upper part of the popliteal space. The circumference of the knee over the middle of the left patella was 13¼ inches; over the right patella it was 11¼ inches. The circumference of the right thigh, upper border of patella, was 11 inches; left thigh, upper border of patella, 13¼ inches; right thigh, one inch above patella, 11⅛ inches; left thigh, one inch

above patella, 12⅝ inches; right thigh, three inches above patella, 13 inches; left thigh, three inches above patella, 13½ inches; right thigh, six

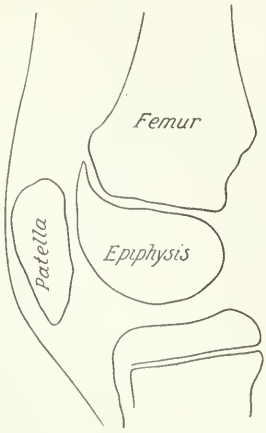
Case IV.—Separation of lower femoral epiphysis. Anteroposterior view taken immediately after the accident. Compared with the normal knee showing shortening, displacement and rotation of lower epiphysis of femur.

inches above patella, 15¼ inches; left thigh, six inches above patella, 15⅜. The crest of the tibia was apparently on a level with the an-

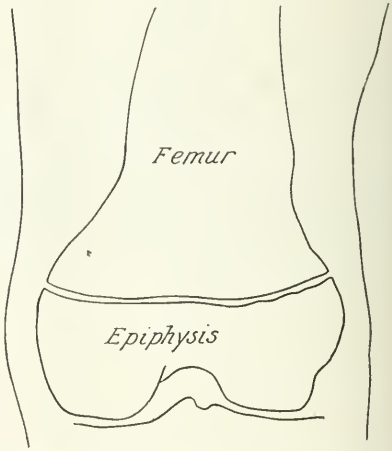
Fig. 12.



Case IV.—Separation of lower femoral epiphysis. Lateral view nine months after accident. See femoral epiphysis. Compare with Fig. 10, before operation.

terior surface of the patella, the tibia having been forced forward and at the same time drawn upward toward the lower end of the diaphysis of the femur. Great lateral mobility existed at the knee-joint. The lower end of the femur (its epiphysis) could be palpated lying above the patella. The nature of the accident in a boy eleven years, the shortening of the leg, the deformity in lateral view, and the lateral mobility at the knee-joint, led me to make a diagnosis of separation of the lower femoral epiphysis. The Roentgen ray confirmed this diagnosis and located the exact situation of the fragments. Under ether anesthesia, the thumbs were placed upon the separate epiphysis while, with the hand and fingers grasping the thigh below the knee, great pressure was exerted upon the epiphysis which was felt to slip over the lower end of the femur into its proper position. Measurement showed both legs the same length. The knee was then immobilized by a plaster-of-Paris splint extend-

Fig. 13.



Case IV.—Separation of lower femoral epiphysis. Anteroposterior view nine months after the accident. Note thickening of lower part of humeral shaft, seat of callus and periostitis corresponding to the area of denuded bone. Compare with shaft of normal femur (Fig. 9).

ing from the toes to the groin, the limb being in a slightly flexed position. At the end of one week upon careful inspection the deformity was found to have recurred. An open incision was then made, as reduction by manipulation was impossible. An incision was made parallel to the long axis of the leg over the displaced diaphysis of the femur. A short transverse incision was made at right angle to the longitudinal incision to gain access to the epiphysis. By means of periosteum retractors, inserted above the epiphysis and below the diaphysis, great traction and counter-traction were exerted upon the epiphysis and diaphysis respectively, until the epiphysis was reduced. The periosteum was found stripped off the lower one-fourth of the shaft of the femur. The leg was

put up in a plaster-of-Paris splint with the knee flexed at an acute angle. In this position there seemed to be less likelihood of displacement. The boy made a good recovery. Several attempts were made under ether to make passive motion during the first two months after the operation. The present condition (ten months after the operation) is as follows: The left thigh is ½ inch less in length than the right; the left thigh is 1/2 inch less in circumference, and the left calf 1/2 inch less in circumference than the right. Flexion is possible beyond a right angle. Extension is very slightly limited. The boy walks with a slight limp, which is growing less as he regains confidence in the limb. He has now good functional use of the knee on that side. The tracings of the skiagraphs after the operation are extremely interesting. The periostitis along the lower end of the shaft of the femur corresponds to the area of bone denuded of periosteum as seen at the operation. (See Figs. 9 to 13, inclusive.)

CLINICAL MEMORANDA.

A UNIQUE CASE IN OBSTETRICS.[1]

By FREDERICK H. PARKER, M.D.,
OF AUBURN, NEW YORK.

In April, 1897, I attended a young woman during her first confinement; everything passed off normally and easily and recovery obtained without incident.

About four or five months after the birth of this child the mother came to me stating that "she feared she was in trouble again; that she was nursing the child; that five or six weeks after the confinement she menstruated regularly (once or twice) and had seen nothing since, and believed that she was pregnant." I told her women were sometimes menstruated irregularly when nursing, and to leave it for another month or so, and return for examination.

I heard nothing more for several weeks, when one day she came in, and said "she was all right, had menstruated with a profuse flow (although not sufficient to disable her) and felt that she had been unnecessarily alarmed. I saw her occasionally after this, and she always acknowledged being in good health, and menstruated regularly until the winter of 1899. In the early spring she came to me and said she was pregnant and would need my services the last of December.

All went well (with the exception of an occasional aching in the right side) until the day before Christmas, when her husband came to me and said "two small cords have been hanging outside for twenty-four hours, with occasional light pains, and considerable backache." I hastened to her expecting to find a prolapsed funis. Instead, I was surprised to find two little legs, each about as large as a small lead-pencil, presenting, with the cervix about one-half dilated, and membranes intact.

I introduced two fingers into the cervix, and without much effort extracted the skin and skeleton of a fetus about six inches long, which looked as though it had been put through a clothes-wringer (the viscera and brain had entirely disappeared) a small shrivelled umbilical cord being attached which broke off. Labor did not come on at once, but twenty-four hours later I delivered her of a well nourished and healthy infant of ten pounds. On examining the secundines I found nothing to indicate a placenta, excepting a portion of the sac of the infant, about four inches in diameter, which was thickened to about one-eighth inch. The mother made an uneventful recovery.

We hear of certain cases of superfetation, but it seems queer to me that a woman should carry a dead fetus for two years and then conceive again, and go through a normal, healthful gestation to full term.

A CASE OF BRAIN TUMOR, WITH EXHIBITION OF SPECIMEN.[1]

By HUGH T. PATRICK, M.D.,
OF CHICAGO, ILL.

The patient from whom this brain was removed was thirty-five years of age and presented an interesting sequence of symptoms. He was time-keeper in a large billiard-hall and had contracted syphilis about nine years before the first symptoms of his last illness. It was first noticed that he began to be inaccurate in figuring up the amounts due, and the cashier found he was making mistakes. One day he had an apoplectoid attack, fell, and is said to have had a convulsion, although the history is not clear as to this. He was unconscious for a time, and on recovery his right side was found to be weak. This disappeared quite rapidly and he resumed work, but some time afterward he had two similar attacks, more severe, and attended with convulsive movements. Following these attacks the use of the right arm became impaired. He was sent to me by Dr. McMartin while I was out of town, and Dr. S. J. Walker took a careful history, examined him carefully, and concluded that the case was one of general paresis. On my return to the city I examined the man and concluded that it was not a case of general paresis. While the man had most of the mental symptoms of general paresis, was cheerful, inclined to joke and be facetious, had tremor of the tongue and of the lips, impairment of memory and stumbling speech, as well as pronounced increase of the knee-jerks, his pupils were equal and normal in every respect and he had decided paresis of the right arm. On account of the distinctly focal character of the paresis of the right arm, more than for any other reason, I believed the case to be other than general paresis. After a few weeks I made a more careful exam-

[1] Read at a meeting of the Chicago Neurological Society.

ination and found wasting of the muscles of the right arm, with partial reaction of degeneration, which rather inclined me to go back to Dr. Walker's diagnosis. The man had had syphilis some nine years previously, for which he was thoroughly treated here and at Hot Springs, but not for any great length of time. By this time he was having occasional spasms of the right arm, after each of which it would be much weaker for a time, then it would recover its previous strength, which, as stated, was not normal. He was placed on very active syphilitic treatment and improved considerably. His mental condition improved the most; the paresis of the right arm improved very little. He was so well mentally that his two brothers told me he was as well as ever, which, however, was not the case. There was still some mental impairment, and his speech was not quite as fluent as it should have been, although much better than before. The previously existing tremor, general nervousness and insomnia disappeared. Then he came to a standstill, improved no further and after a little time the localized spasms of Jacksonian fits in the right arm became more frequent and severe. He had neither headache, dizziness, vomiting, nor tinnitus, and choked disc was absent, so that tumor of the brain was excluded. The diagnosis lay between general paresis and brain syphilis, and, finally, I excluded the former because he did not get worse, and because the symptoms of paresis had cleared up considerably under specific treatment. I concluded that it was a case of syphilitic arteritis; that he had had three severe attacks of thrombosis, and that one of these had left a cicatrix in the cortex which had become non-progressive, which could not be improved by treatment and which accounted for the weakness in his right arm, as well as for the Jacksonian fits, because thrombosis is frequently the result of syphilitic arteritis, more frequently cortical than deep, and a cortical lesion, whatever it may be, is ordinarily the cause of focal fits. The case seemed to follow out my diagnosis nicely, for one day the man apparently had a more severe and extensive thrombosis, which left him with complete right hemiplegia, followed three weeks later by another attack coming on in the night, from which he died after three days. On looking at the brain after removal there was nothing abnormal to be seen on the surface, except a slight adhesion at one place over the arm center, on the left side where the pia had been adherent to the dura. Before cutting in to the brain, I attempted to locate the fissure of Rolando, but could not do so, which confused me not a little. Then I stripped off the membranes until satisfied that I had the fissure, which I found to be greatly distorted, the middle of it having been pushed forward. On incision at this point, I discovered a tumor larger than an egg. Dr. Herzog kindly made a microscopic examination and reports that the growth is a glioma. When the brain was removed and placed on the table, I do not believe any man could tell whether or not there was a tumor in its substance. It is a question whether, if an incision into the brain had been made during life for the purpose of removing the growth with the oozing of blood which would have followed, even after careful ligation, it would have been recognized as a tumor if cut into, as the consistence and color were very much like that of the brain itself.

OBSERVATIONS ON A SPIRILLUM OCCURRING IN FALSE MEMBRANE ON THE TONSIL.[1]

By CHARLES F. CRAIG, M.D.,
OF SAN FRANCISCO, CAL.;
ACTING ASSISTANT-SURGEON U. S. A., LATE DIRECTOR OF THE BACTERIOLOGICAL LABORATORIES OF THE STERNBERG U. S GENERAL HOSPITAL, CHICKAMAUGA PARK, GA.

The number of spirilla as yet described is comparatively small, and this is especially true with reference to those occurring in the human body. The cholera spirillum of Koch, the spirillum of Obermeier and the Finkler-Prior spirillum are the best known of this class of micro-organisms, but in addition to these a few others have been described as occurring in man, in health and in disease. The following list includes the spirilla which have been found associated with man and is, as far as I know, complete.[2]

Spirillum choleræ asiaticæ, of Koch, found in the discharges from, and in the cadavers of, cholera patients. It is aërobic or facultative anaërobic, sometimes produces pigment, liquefies gelatin, and is motile. *Spirillum Obermeieri,* found in the blood of sufferers from relapsing fever. Has not been cultivated. *Spirillum of Finkler and Prior,* found in the discharges from patients suffering from choleræ nostras. It is aërobic, facultative anaërobic, liquefies gelatin, and is motile. *Spirillum sputigeneum* of Miller, found in the sputa in health. Has not yet been cultivated. *Spirillum dentium* of Arnt, found beneath the margins of the gums in healthy individuals. Has not been cultivated. *Spirillum or vibrio nasale of* Weibel, found in nasal mucus. Is aërobic, facultative anaërobic, does not form pigment or produce liquefaction of gelatin, and is motile. *Spirillum of Miller*, found in carious teeth. Is aërobic, facultative anaërobic, liquefies gelatin, and is motile. Does not produce pigment.

It will be seen from this list that our knowledge of the pathogenic spirilla is very limited, and each new fact concerning them is of interest.[2] I have, accordingly, in this paper briefly described a spirillum which was found in immense numbers upon and in a false membrane occurring in the tonsil. The history of the case is as follows:

Lt. R., a young man, complained of difficulty in swallowing and soreness of the throat on the right side. He did not have headache, fever, nor other constitutional symptoms. Examination of the throat showed an enlarged, slightly reddened

[1] From the Bacteriological Laboratory, United States General Hospital, Presidio, of San Francisco.

[2] In Migula's latest monographic systematic treatment of this group, it is to be noted that most of these forms are relegated to the genus microspira. [Ed.]

right tonsil covered with a thick, dirty, white membrane, which occupied the posterior portion and extended to the surrounding mucous membrane of the fauces. The left tonsil was normal in size. The throat appeared somewhat inflamed in the region of the affected tonsil. The false membrane, upon closer examination, appeared irregular in contour, with sloping edges and uneven surface. It could be easily removed and left a smooth and but slightly reddened tonsillar surface beneath. The patient was ordered treatment and in a few days the membrane disappeared. An antiseptic gargle was used. Cultures on Loeffler's blood-serum were taken as the membrane looked like that of diphtheria.

Description of the Spirillum.—A portion of the membrane removed and examined by means of the microscope showed it to be composed of degenerated epithelium and of an immense number of very active spirilla. Cocci and bacilli were also present, but in very much smaller numbers. These spirilla were large, from 20 to 35 mikra in length, but very narrow. They resembled much the spirilla of relapsing fever in their size and shape and formed, in some places, large, entangled masses. They were very active, their movement being serpentine in character, as a rule, and very rapid, but sometimes vibratory and rotatory. In looking at a field filled with the spirilla, they resembled nothing so much as a mass of wriggling little serpents. The membrane was found to be composed almost entirely of epithelial débris and these bacteria. As it was thought that, perhaps, this organism might be either the spirillum described by Miller or Arnt, smears were made from material taken from under the gums and from between the teeth, but the spirilla were not found in them. They seemed to be limited entirely to the false membrane. They were very slender in comparison with their length and presented a homogeneous appearance throughout.

Staining.—They stained readily with all the ordinary aniline stains, as methylene blue, fuchsin, gentian violet, etc., but not very intensely. They stained uniformly throughout, there being no metachromatic granules present. Carbolic fuchsin seemed to stain them better than anything else. They invariably decolorized when Gram's method was employed.

Culture.—The blood-serum tubes first inoculated showed nothing but a mixed culture of staphylococci and a short, thick bacillus. Cultures were afterward made upon agar, blood-serum, and bouillon, but were always negative, showing that the organism could not be artificially cultured upon the ordinary nutrient media. This fact, together with the uncertainty caused by the mixture of organisms in the membrane, rendered animal experimentation useless.

The only spirilla occurring in the mouth with which these organisms might be confused are those of Miller and Arnt, but the morphology of these organisms is entirely dissimilar. These are much longer and narrower, while the fact that they could not be found around the teeth nor in scrapings from under the gums removes all doubt concerning their identity with the spirilla described by the investigators mentioned.. The occurrence of spirilla in this situation in such large numbers is very interesting and their strict localization in the false membrane and tonsil would indicate that they were instrumental in the etiology of the condition present. In making smear preparations especial care was taken to secure material from the crypts of the tonsil, which were filled with exudation, and in such smears the spirilla were found in almost pure culture. Bleeding was not produced when the membrane was removed nor when the tonsillar crypts were emptied. Constitutional symptoms were not present and the only local symptom was the soreness of the throat. The membrane was thick and rather pulpy in consistence and very closely resembled, on inspection, a diphtheritic membrane, but here the resemblance ceased, as it was not adherent nor did it leave a raw or bleeding surface when detached. It differed from the exudation occurring in tonsillitis in that it was so easily removed, even from the crypts, while the tonsil itself was but little enlarged and not very painful.

The chief points of interest connected with this organism are: Its large size, its extreme activity, its decolorization by Gram's method of staining, and its occurrence in almost pure cultures in a false membrane of which it formed a considerable part, and in the crypts of the diseased tonsil. The case is of further interest because of the resemblance of the false membrane to that of diphtheria, and as showing the value of a microscopic examination of the exudate in all tonsillar affections.

MEDICAL PROGRESS.

Apomorphine in Tachycardia.—Attacks of tachycardia, idiopathic in nature, or accompanying valvular lesions, are oftentimes only slightly amenable to treatment, and any new, successful remedy is gladly received. P. Zenner (*N. Y. Med. Jour.*, March 3, 1900) claims that he has been successful in stopping such attacks in several cases by the hypodermic use of apomorphine in doses sufficient to cause nausea and vomiting. After being used in the same case for several attacks it seems to partially lose its power.

Camphoric Acid in Night Sweats.—At a lecture given at the Cleveland General Hospital, by J. B. McGee (*Bull. Cleveland Gen. Hospital*, Oct., 1899) reports on the value of camphoric acid as an antisudorific especially in the colliquative sweats of tuberculosis. There are other agents, as atropine, for example, which may be equally efficient, but whose coincident effects are disagreeable. Camphoric acid rarely disagrees with the patient and may be given either dry on the tongue or in a wafer. Fifteen to twenty grains are usually sufficient, although much larger quantities have been used with no serious results. It

is best given shortly before bed-time for its absorption is slow. When taken for a time it is said also to lessen the profuse expectoration so often present.

Pathology of Serous Inflammations.—By the injection of turpentine and iodine into the pleural and peritoneal cavities of animals, R. Heinz (*Münch. med. Woch.,* Feb. 18, 1900) has been able to study the minute changes caused by these irritants. With turpentine the membranes appeared covered with numerous sharply circumscribed vescicles consisting of aggregations of leucocytes, which in the center of the mass had undergone necrosis. In the immediate vicinity of these heaps the serosa was degenerated and the underlying external muscular coat of the gut also participated in this change. Owing to the fact that connective tissue cells were intermingled with the white cells, it was safe to infer that the exudation took place into and not upon the superficial layers of the tissue. With iodine a rich deposit of fibrin occurred and the author, being mindful of the disputed origin of this substance, followed the pathological changes from their earliest appearance in the hopes of obtaining direct evidence of fibrinous cell-degeneration. Microscopically the exuded matter was found to be made up of a network of fine fibrillæ, but no tissue cells were present. In other sections, opaque spots were seen studded through the field, which proved to be normal desquamated elements from the superficial layers of the serosa. Furthermore, the layer of endothelium was not infrequently seen to pass under the fibrin placques, which, of course, demonstrated that the latter were exudations from the capillaries and no direct proof of the cell origin of the fibrin could thus be obtained. In the later stage, the endothelium took on marked proliferative action with the formation of numerous villous processes covered by embryonal cells, the subjacent lung tissue shared in this process and a cross section here gave a picture not unlike that of acinous glands. In the peritoneum the injection of iodine was followed by agglutination between the coils of intestine. Preceding this, however, there always was a falling-off of the endothelial cells, which normally prevent adhesion between adjacent tissues.

Ureteral Calculus.—H. A. Kelly (*Jour. Am. Med. Assoc.,* March 3, 1900) reports a case of ureteral calculus in the diagnosis and treatment of which several new features were introduced. The patient had an attack of renal colic after unusual exertion. There was no abdominal tenderness, but vaginal palpation revealed a hard oblong body in the left ureter. This was exquisitely tender and was situated half-way between the internal urethral orifice and the cervix. Cocaine was injected into the tissues about this mass, through the vaginal wall. The cystoscope revealed an abdominal left ureteral orifice, with everted, reddened mucous membrane. A ureteral sound failed to elicit a click. The orifice was determined to be strictured, so a dilator was introduced and the orifice stretched. After the ureteral sound failed to detect a stone, the end of an ordinary renal catheter was dipped into a mixture of melted wax and olive oil, which forms a perfectly smooth bulb on the catheter tip. This was introduced into the ureter without touching anything, and pushed up to the kidney. When it was withdrawn, the wax showed a series of parallel scratches from end to end, which could have been caused only by a stone. A slight fragment of stone also adhered to the wax. Since the ureter above the stone was dilated it was found impossible to grasp the stone, so the ureteral orifice was again carefully stretched and the patient placed in bed. Inside of twelve hours the stone came out with difficulty. The use of cocaine in this region opens up an interesting field. The ureter could be opened through the vagina, for the removal of a stone. The wax-tipped bougie demonstrated the presence of stone after the sound had failed, and if the catheter were waxed at intervals from the tip down one could quickly determine the precise location of the stone.

Cinnamic Acid in Consumption.—The stir caused in medical circles within recent years by the reports of undoubted cures of tuberculosis by the use of cinnamic acid injections has led F. Fränkel (*Deutsch. Arch. f. klin. Med.,* Bd. 65, Hft. 5 and 6) to thoroughly review the subject and to add some experience of his own, which on the whole, however, are not encouraging. Severe cases showed but a transient relief and soon a return of the old symptoms with increased force. Of more favorable subjects, twelve received systematic intravenous injections for seven weeks, with the result that 3 died during this time, 1 became worse, 3 showed no change and 5 experienced some relief, but of these only one to a marked degree. Hemoptysis was frequently brought on by the injections. Laryngeal phthisis gave still greater disappointment, as did also lupus, which did not seem to react at all except when the acid was directly injected into the nodules; this, however, might have been due to the alcohol used as a solvent. By inoculating rabbits with tubercle bacilli and then at once resorting to long-continued injections of cinnamic acid, absolutely no immunizing powers could be detected.

Benzoic Acid and Urine.—The effect of benzoic acid in restoring the normal acidity of urine is well known. Having noticed in a number of cases that benzoic acid seemed to have little or no influence in increasing the acidity of urine already normally acid, William W. Ashhurst (*Phil. Med. Jour.,* Feb. 24, 1900) experimented as follows upon two dogs. The urine of the dogs was first tested for some days to ascertain the average normal acidity, the tests being made of each portion as it was passed, and of the whole twenty-four-hour quantity at the end of that time. The method of determining the degree of acidity was to take 1 c.c. of urine mixed with 10 c.c. of water and 1 c.c. of a one per cent. alcoholic so-

lution of phenolphthalein, and to allow a one per cent. solution of potassium hydrate to slowly run in from a burette, noting the quantity of the latter required to produce a distinct pink tinge. Later each day was given daily one gram of sodium benzoate hypodermatically for a number of days and similar tests made, and still later two grams were given daily. The writer presents the results of twenty-two tests made under these three different conditions. He also noted for a number of days the quantity, the specific gravity, and the acidity of his own urine. Then he took six grams of sodium benzoate daily for a number of days and noted the same points, and found by comparing the averages that while taking the sodium benzoate the specific gravity was scarcely changed, the quantity of urine was somewhat increased and the acidity slightly diminished. These results corresponded with those obtained from the examination of the dog's urine. He also found that the administration of sodium benzoate had a most marked and positive influence in indefinitely postponing the occurrence of the alkaline fermentation. This explains the well-known effect of benzoic acid on ammoniacal cystitis. It is not that acidity is increased, but that ammoniacal fermentation is prevented from taking place in the residual urine. Judging from the well known beneficial effect of benzoic acid in cases of cystitis where there is no residual urine and no ammoniacal fermentation taking place, it would seem that this acid has a distinct germicidal or antiseptic action. In a specimen in which the presence of bacteria was noted, they were notably less while the benzoate was being given. Ashhurst sums up the effect of benzoic acid upon the urine thus: There is (1) an inconstant diuretic action, accompanied by a slight diminution of the acidity of the urine; (2) a retardation or absolute prevention of the occurrence of alkaline fermentation; (3) an action in nature germicidal or inhibitory, to the growth of certain micro-organisms either within the bladder or when introduced into the urine after voiding, these susceptible organisms including especially those which tend to produce the alkaline fermentation, but which develop in the urine while it is still acid.

Ligation of Hemorrhoids.—J. B. Bacon (*Jour. Am. Med. Assoc.*, March 3, 1900) believes success in the operative treatment of hemorrhoids depends so much on careful attention to detail that he publishes his technic. At night, pil. hydrarg., gr. vi, is given. Next morning on an empty stomach, a Seidlitz powder is given and repeated every half hour until the movements are free from fecal matter. Until the second day thereafter the patient is kept on a liquid diet and strychnine, gr. $^1/_{30}$, every six hours, and the operation is then performed. With acutely inflamed piles the operation is done as soon as the bowel is empty. The patient and the operator's hands and instruments must be thoroughly clean. For ligatures, fine silk is to be preferred, since coarse silk can not be tied tight enough to cut through the pedicle in three or four days, and is apt to leave a bleeding-point when it is finally carried away. One should remove the redundant skin-tags opposite the internal piles. In most cases the anastomotic veins, between the internal and external groups of veins, are varicosed, and must be dissected out and ligated. This insures the patient against a recurrence. After the piles are removed the operative field is well irrigated, a half-inch rubber tube, wound with sterile gauze, smeared with vaseline, to an inch diameter, inserted with the aid of a bivalve rectal speculum three inches (*i.e.*, above the circular fibers of levator ani) and a dressing firmly fastened on. This tube is left four days when a Seidlitz powder is given before breakfast, and repeated in one-half hour. As soon as the bowel feels like moving a two-quart enema is injected through the tube which is then plugged. The tube and gauze will be passed with the movement, with little disturbance of the wound area. The wound is washed daily with 1-2000 corrosive sublimate solution, after the bowels have been moved by enema. For ten days the patient must use a bed-pan, since a movement in the sitting posture invariably tears the wound area open. The occasional incidence of post-operative hemorrhage necessitates a careful watch for the constitutional signs of bleeding, since the blood collects in the rectum. One should take special notice after each movement, since hemorrhage usually results from a ligature being prematurely torn off.

Gastrostomy.—J. Braquehaye has written a monograph on gastrostomy (Paris, Ballière et fils, 1900) in which he enumerates twenty-five different methods establishing a gastric fistula. He especially advocates that of Fontan, which is essentially as follows: The abdominal wall is incised and the stomach seized with a pair of forceps as near the lesser curvature as possible. A portion of it is drawn out of the wound in the form of a little cone. The base of this cone is stitched to the abdominal wall (visceral to parietal peritoneum), and the point of the cone is pushed into the gastric cavity. The wound in the abdominal wall, and the folds in the stomach at the base of the cone, may be narrowed by stitches, after the point of the cone has been punctured with a fine scalpel and a soft rubber catheter, No. 24 F., introduced.

Iodophile Leucocytes.—Following the researches of Czerny, in 1893, and of Kaminer and others since, F. Hofbauer (*Centralb. f. Innere Med.*, Feb. 10, 1900) reports extensive studies of these leucocytes in diseases of the blood. He used an air-dried blood spread and exposed it for one minute to a mixture of iodine one part, potassium iodide three parts, water one hundred parts, and acacia to give a syrup consistency. The findings so far indicate that in pneumonia, primary pernicious anemia, and well-marked leukemia, and sometimes in pernicious anemia secondary to severe disease, some or all of the leucocytes contain a substance which stains red with iodine. Apart

from these conditions a distinct iodine reaction, even in only a few of the leucocytes, indicates that an active process of suppuration is going on. The staining substance may be in the form of irregular granules, or be diffused throughout the cell-body.

Heroin.—As a respiratory sedative, R. L. Daly (*Boston Med. Surg. Jour.*, Feb. 22, 1900) finds that heroin has the following advantages over morphine: (1) It prolongs respiration, and at the same time increases the volume of each respiration, making it a remedy much to be desired in the treatment of cough; (2) it is not a hypnotic; (3) absence of danger of acquiring the habit; (4) it does not weaken the respiratory apparatus; (5) it does not cause unpleasant disturbance of the stomach or intestines; (6) it can be prescribed in cases in which heart complications occur; (7) the ratio of the therapeutic dose to the toxic dose is considerably smaller than that of morphine. He cites in detail seven cases of pulmonary tuberculosis and one of tubercular laryngitis taken at random from over one hundred cases in which he has administered the drug, illustrating its prompt and beneficial action on the cough, respiration, and secretion. In all these cases, after other drugs had been tried without success, in about three days after the administration of heroin, in half-grain doses three times a day and once at night, was begun, the cough became loose and less frequent, expectoration became free, and there was less dyspnea. At the end of a week there was no dyspnea, the cough had diminished to a marked extent or had disappeared, and all pain was absent. From the beginning of the administration of heroin the respirations, carefully noted in nineteen cases, were decreased in number from two to seven per minute. In certain cases when the drug was stopped for a week the respirations again became more rapid. The effect of the drug upon night-sweats was also marked. In one case almost everything had been given to diminish the night-sweats, but without avail. Then heroin, gr. ½ t.i.d. and at night, was administered in addition to atropine sulph. gr. $^1/_{50}$, at night and on the third night of its administration the sweats decreased to a great extent, and on the fourth ceased altogether. Atropine sulph. had been given with mist. codeine for some nights in this case without result before the heroin took the place of the mist. codeine. In the case of tubercular laryngitis, heroin, gr. $^1/_{12}$ every three hours, kept the throat in a condition of anesthesia and relieved the sore throat and the pain very considerably.

Prognosis in Appendicitis.—After considering the pathology of appendix lesions, H. A. Coley (*Lancet*, Feb. 10, 1900) proceeds to the question of prognosis, which depends on the virulence of the infective agent, and on the nature and extent of the process in the appendix itself, and more particularly in the general peritoneal cavity. Clinically the prognosis must be arrived at by balancing the data derived from the local symptoms, local signs, general symptoms and the progress of the case. Of the local symptoms pain is the most constant, the distribution, character and severity of which are of much significance. The initial pain is usually in all cases referred to the umbilical region or the general abdominal cavity. In mild cases it soon localizes itself in the right iliac fossa: In perforative cases it is more sudden, more severe, and more persistently generalized. Pain associated with definite collapse assumes maximum importance since it indicates perforation, or rupture of an abscess wall. An interval of quiescence following an acute onset of pain must not mislead. In some cases there is a dull aching pain or slight colicky pains for a day or two, and then a paroxysm of acute pain with vomiting and febrile disturbance, the later pains being due to peri-appendicular inflammation. Sudden increase of pain in any case calls for most careful consideration and often indicates operation. Persistence of severe general pain is usually evidence of a grave lesion, since in mild cases it soon becomes localized and less intense. Persistent severe pain localized to the appendix is especially apt to accompany concretion. Pain much increased by respiration indicates peritonitis. While the kind, onset, severity, and persistence of pain are important indicators, yet it must be distinctly remembered that there may be a very severe lesion of the appendix, especially gangrene, with little or no pain. Vomiting may accompany, precede or follow the pain, but is usually an initial symptom. Frequent, severe, and especially persistent or recurrent vomiting indicates a serious lesion. Absence of vomiting proves nothing. Natural action of the bowels is favorable. Persistent hiccough is unfavorable. Among the general symptoms are two useful guides, the temperature, respiration and pulse considered conjointly, and the general aspect of the patient. Temperature alone is misleading. In at least four appendical conditions it may be normal or subnormal, *viz.*, collapse after perforation or gangrene; general septic peritonitis; strictly circumscribed abscess, and mild appendicitis without peritonitis. High fever continued for the first few days usually means a severe infection. A fall of temperature, if accompanied by general improvement, is reassuring, but not otherwise. A secondary rise of temperature means spreading infection. Fever persisting after eight or ten days means local abscess, and becomes intermittent or remittent. The pulse is of more prognostic value, but one must be careful to consider its relative, rather than absolute, frequency, and its temporary character rather than any temporary alteration. High pulse means a severe infection, very often wide peritoneal infection, especially if pulse-rate and temperature are disproportionate. A pulse-rate above 120 leads one to expect local suppuration or general peritonitis. Rapid, shallow respirations indicate peritonitis. Of local signs, immobility is constant, at first localized to the right side. If it becomes general it means

general peritonitis and the prognosis is correspondingly grave. Distention may or may not be present, but when marked is of grave omen. The area of tenderness gives an idea of the extent of peritoneal inflammation. Persistent or increasing local tenderness may be almost the only sign of localized suppuration. Tumor or deep-seated resistance is very common but is often not discernible, so that it is of limited prognostic significance. On the whole, the presence of a tumor is reassuring as it indicates a localization of the process. The course of the disease during the first twenty-four hours furnishes important data as to prognosis based on the above observations. One must always be on his guard against a treacherous remission of symptoms. As to recurrence, various observers estimate from 30 to 50 per cent. of recurrences in cases not operated on. Recurrence usually appears within the first year. A mild first attack is often followed by recurrence. If convalescence is slow, with persistent local pain, tenderness, or swelling, the probability of recurrence is great. If, in the interval, there is occasional pain, irregularity of the bowels, local tenderness or rigidity, chronic appendicitis probably exists.

Genito-Urinary Diseases.—After briefly reviewing the different means employed in different cities of the world to control or suppress prostitution, Ferd. C. Valentine (*Jour. Am. Med. Assoc.*, March 3, 1900) gives as his opinion that it is impossible for the State to regulate prostitution. If the State cannot regulate prostitution, can it suppress genito-urinary diseases? It is shown that even regular examinations of public prostitutes do not prevent them from becoming infected with gonorrhea and inoculating those with whom they have connection during the time from one examination to the next. But statistics seem to show that more men are infected from so-called "respectable women," *i.e.*, clandestine prostitutes, than from public prostitutes. There is, therefore, a source of infection which can be controlled in no way by the State. Inasmuch as illegitimate relations between the sexes cannot be prevented, and regular examination of public prostitutes does not necessarily prevent infection, while clandestine harlots cannot even be examined regularly, Valentine thinks that education as to the dangers of gonorrheal infection, and its sequelæ, must be the means used against the invasion of the disease. He has found in men, otherwise highly educated, a most complete and criminal ignorance of even crude outlines of genito-urinary physiology, and to this ignorance they owed their sufferings. If a man knows that the gonococcus may invade all parts of his organism, that he may lose his life from gonorrhea, that he may become hopelessly blind in consequence, that he may become a mental and physical wreck, and that the disease may, through him, cause the death and disabling of others, perhaps innocent ones, he will not neglect himself when he becomes infected, but will seek a reputable physician, that the disease may be cured as quickly as possible, thus striving to prevent its invasion into deeper and more remote organs. The writer makes the following suggestions: (1) Sufficient of the physiology and pathology of the genito-urinary apparatus should be taught in institutions for higher education, to convey to students the dangers of genito-urinary diseases to themselves and to others; (2) similar instruction should be given in schools attended by boys at the age of puberty; (3) no man who has ever had gonorrhea should be allowed to marry until it is proved by a physician that he cannot infect his wife; (4) regular physicians should be elected, by their societies, to deliver evening lectures to the public on genito-urinary diseases; (5) every father should be taught to warn his sons of the dangers of genito-urinary diseases; if the father is unable to do so, the family physician should do it; (6) every medical society should elect its most competent member to write at least one article on the subject, worded for laymen's comprehension, and to be published under the auspices of the society.

Pelvic Inflammations.—In cases of metritis and salpingitis Labadie Lagrave (*Jour. de Méd. de Paris*, Feb. 11, 1900) cleanses the vagina with 1 to 2000 mercuric chloride solution, inserts a laminaria tent, and packs the vagina with iodoform gauze. After twenty-four hours a larger tent may be inserted, and when the cervix is well dilated an intra-uterine douche is given, and the uterus packed with iodoform gauze soaked in creosote-glycerin (1 to 3). In carrying out these procedures the cervix should not be drawn down, as traction on the peri-uterine structures may provoke an extension of the existing pelvic inflammation. The packing is to be renewed every four days for two or three weeks. If the uterine mucous membrane is rough with hypertrophied papillæ and villosities, the above treatment should be preceded by curettage, care being taken to curette about the mouths of the Fallopian tubes so that these may drain freely into the uterus. Metritis, lymphangitis, and even salpingitis are often thus cured without resort to operation; and even if the uterine orifice of the tube is obliterated, the salpingitis, although not cured, will be benefited by the reduction of the general inflammation. The author advises against laparotomy except in cases of very large pus-tube.

Dublin Fever.—This is the name given to a form of influenza by H. FitzGibbon (*Dublin Jour. Med. Science*, Feb., 1900). He divides influenza into three classes: (1) Simple influenza, the ordinary mild form; (2) pulmonary influenza, a severer form, complicated by bronchitis or bronchopneumonia, and (3) enteric influenza. This third form begins with chilliness, languor, pains in the back and limbs, and a dull frontal headache. This is followed in a few hours by an intense febrile disturbance, 104° to 106° F., with its usual accompanying symptoms, which persist twenty-four to forty-eight hours and subside rapidly. The temperature may fall below normal.

The condition of the patient, however, does not improve with the fall of the temperature, but the distressing symptoms persist and there is a condition of great nervous prostration, with insomnia and mental disturbance, similar to the neurasthenia of chronic alcoholism. With this nervous prostration there sets in a train of gastro-enteric symptoms, difficult to distinguish from those of typhoid fever, but without the characteristic temperature and diarrhea of that disease. This continues for an uncertain period, depending upon the resistive power of the patient. FitzGibbon was impressed by the similarity of severe cases of this class of so-called influenza to Chagres fever. Chagres fever is a malarial fever occurring on the coast of the Caribbean Sea and is due to malarial infection emanating from vegetable matter in the swamps along the coast. The close resemblance of this form of influenza to Chagres fever led the writer to look for a similar source of infection in Dublin. He found numerous places in the city where there were accumulations of decaying vegetable matter, ashpit refuse, and filth, whose abominable vapors were blown over the city. Most important is the fact that he found many houses built, or being built, upon sites filled in with ashpit refuse and other rubbish containing vegetable matter and filth. He thinks that the vapors arising from such building-ground and from the refuse depots and other collections of decaying vegetable matter and filth in the city are the cause of the high death-rate and of the malarial type of enteric influenza, which may as justly be called Dublin fever, as the fevers of Chagres, Malta, or Gibraltar derive their names from the places whose insanitary conditions produce them.

Colostomy by Strangulation.—M. Gangolphe (*Rev. de Chir.*, Feb., 1900) describes a method of iliac colostomy by ligature and strangulation which he has performed sixteen times with satisfaction to himself and his patients. The opening in the abdominal wall is made small to prevent prolapse and hernia. The gut is drawn out of the wound and stitched to the parietal peritoneum, in such a manner that three or four inches of it protrude. Through its meson, close to the level of the skin, two interlocking stout ligatures are passed and tied around the afferent and efferent limbs of the loop of bowel. They are tied as tight as possible, the object being to strangulate the gut. In this they succeed in some forty-eight hours, the patient meanwhile having suffered colicky pains of slight character. The gangrenous distended loop of bowel is then opened with a thermocautery, and the constricting ligatures, having fulfilled their mission are cut and slipped off. The appearance of the wound at this stage is said to be somewhat alarming, but the writer says that it may be safely left to the restorative power of nature. In time the sloughs come away and a double-barrelled anus is left, the upper afferent end, having usually the larger caliber, although not always so. There is no tendency to prolapse, and as the septum between the openings is well marked the passage of fecal matter from the afferent into the efferent portion of the gut does not take place. Sixteen patients were operated on and all recovered. There was generally some fever but the severer symptoms of infection were wanting.

Vomiting of Pregnancy.—Cases of obstinate vomiting in the female are often due to pregnancy, being caused by reflex irritation from the uterus. If as many as two monthly periods have been missed, this, according to G. Davenport (*Obstetrics*, Feb., 1900) should always be thought of, for if not promptly and effectively treated it may result fatally. The treatment for a gastritis will be of no avail, for the vomiting is purely reflex, and there are no lesions either in the stomach or the liver. If ordinary means are of no avail for ten days or two weeks, the uterus should be emptied, and if this procedure has not been too long delayed it is always successful in stopping the vomiting.

Another Eye Accommodation.—Although the eye is such an important organ and so necessary to one's well-being, it is astonishing how often it is almost maliciously misused either by not wearing any glasses at all or by using those which do not correct the refractive errors. N. B. Jenkins (*N. Y. Med. Jour.*, March 3, 1900) draws attention to the power which the eye has of adapting itself to badly fitting glasses and calls this "another accommodation" of the eye. He cites many cases in which glasses were worn, some of them giving partial relief, but which were far from being able to correct the refractive errors. To select a pair of glasses that can be worn is a simple matter, but to properly correct complicated cases for long-continued reading will always be beyond the bungler and the quack.

Hemorrhage after Amygdalotomy.—One of the most difficult of primary hemorrhages to control, and one which is liable to occur in the experience of any general practitioner, is the hemorrhage which sometimes follows the simple abscission of an hypertrophied tonsil. G. B. Hope (*N. Y. Med. Jour.*, March 3, 1900) reports the case of a strong, healthy woman in whom it was evident that a small artery was cut during the operation which was performed under chloroform. The hemorrhage was severe and greatly aggravated by the uncontrollable excitement of the patient and the attacks of coughing necessitated by the presence of blood in her larynx. In these cases, ligation, compression or torsion is practically impossible. The familiar hemostatics, such as cold, cocaine, and antipyrine were ineffective and it was only after the persistent use of the galvanocautery that a fortunate arrest of the hemorrhage occurred. The patient had already lost large quantities of blood and it is probable that this exsanguinated condition had a beneficial effect. The treatment which is advised consists of the use of the galvanocautery, the hypodermic use of ergot, the maintenance of an erect position, and the avoidance of stimulants.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

THE MILK SUPPLY OF LARGE CITIES.

AN abundance of pure water is recognized as the first essential provision in securing the healthfulness of a city, and undoubtedly second in importance is a plentiful supply of good milk. The recent interesting discussion of this subject before the New York County Medical Society (see p. 394) brings out clearly the fact that our American cities are being supplied with milk that is constantly improving in quality. Only a little persistence in demanding good milk is now needed to maintain the standard that during recent years has been attained. As in all economic questions the demand creates the supply.

No after-treatment of milk by centrifugal cleaning, nor even Pasteurization, ever succeeds in making carelessly collected milk as wholesome for general consumption, and especially for invalids and children, as the originally uncontaminated product. It is this branch of reform in the milk industry that needs encouragement. The farmer must be taught the precautions necessary to protect his milk as far as possible from any and all contamination and then must be paid enough for his additional labor and expense to warrant his expenditure. The increased sale of such milk will soon abolish the necessity for any increase of price to the consumer. The improvements that have come in the milk supply have been mainly due to such advice obtained and put in practice through private enterprise.

The arraignment of the present state of affairs in New York City with regard to the absolute prohibition of the sale of skim-milk seems to be completely justified. The sale of skim-milk, like most other good things, is liable to great abuses. It needs most careful regulation. Prohibition, however, is too radical. Skim-milk is an extremely valuable article of food; moreover, it can be obtained for a very low price. To deprive the poor of all opportunity to purchase it because, forsooth, its sale is open to abuse is almost criminally absurd. A medical advisory board would surely put an end to the cruel waste of valuable nutritious material which the present prohibitive regulations involve. The poor of the city can be greatly benefited by being given an opportunity to purchase skimmed milk, when sold as such, at a price proportionate to its value. It has been found perfectly feasible to do this in other cities and it may surely be accomplished quite as well here in New York.

THE LICENSING OF MIDWIVES.

IN view of the fact that a bill is now before the New York State Legislature registering midwives in New York City, it is interesting to know what the medical men of Great Britain think regarding the desirability for such a measure for themselves.

A bill is now before the House of Commons for the regulation of the practice of midwives. In order to learn the exact opinion of the members of the profession upon the desirability of this proposed legislation, the *Lancet* sent out about 20,000 circulars to them, asking an answer to three questions: (1) Are you in favor of legislation for the regulation of the practice of midwives? (2) Are you in favor of the bill now before the House of Commons? (3) Are you indifferent in the matter? Answers have been received from about one-third (6299) of the parties addressed. Of these 1817 consider no legislation necessary; 1323 are opposed to the present bill, although desiring legislation along these lines; 1311 favor legislation on this subject and support the present bill and 596 frankly express themselves as indifferent to the whole matter. The balance were more or less indifferent. The *Lancet*

considers that the opinions thus obtained are fairly representative of the medical sentiment regarding the matter. On this basis it will be seen that only about one-fourth of the profession are in favor of the bill, and fully one-third are absolutely opposed to it.

Regarding the regulation of the practice of midwives in New York City there should be no two opinions. Midwives flourish here in large numbers; by proper regulation, under legal enactments, they can be made to meet an absolute demand that is difficult to satisfy in any other way. As long as a midwife has fitted herself by proper instruction and training to fulfil the functions of that office, all principles of individual liberty on the part of the patient, and every right to earn an honest living on the part of the midwife, justify the existence of the latter. Under a proper system of regulation and wise legislation midwives may become an important and desirable factor in any tenement-house community.

A SCHOOL OF HYGIENIC AND SANITARY SCIENCE.

An interesting feature connected with medical education is to be found in a recent announcement by the Cornell Medical School of the establishment in New York City of a School of Hygiene and Sanitary Science. Referring to the circular of information just issued it appears that the aim of the department is to teach not undergraduates only, but is specially planned to meet the needs of health officers throughout the cities, towns and villages of the country.

Granting that the ordinary physicians understand in a general way such matters as pertain to the health of large collections of people, as a matter of fact the endless details which have arisen from the increase of population and the crowding in great centers have far outstripped the knowledge of the average health officer, and too often this knowledge is acquired by him only after the sacrifice of life and at great public expense. In the primitive community it was a simple enough matter to protect the water supply, to see that the drains emptied below the reservoir, and that the public school had room enough for the pupils who attended it; but with the changes which have taken place in the last decade vastly more complex questions have arisen. The sanitary officer must be able to tell pure from impure water, to trace the source of contamination when it occurs and be able to propose a scheme by which the water can be made safe.

In great cities the impurities in the air are a matter of very serious consideration, also the derivation of these impurities and how to avoid them. The importance of this matter is shown by the reports of the New York Board of Health in following the work of the Street Cleaning Department under the late Colonel Waring, when the death-rate fell about 20 per cent. simply by removing the dirt from the streets and so protecting the atmosphere from contamination. Tenements, hotels, clubs, prisons and all other buildings in which human beings are forced to congregate, are gradually coming under the intelligent supervision of the health officer. The matter of superintending the food supply of great centers of population is another duty which devolves upon the health officer, and it is of the first importance that he should be instructed in the methods of testing the various foodstuffs, such as vegetables, meats, and milk.

Some infectious diseases are exceedingly rare and many men who live in healthy communities have never seen them in their most contagious forms, and, hence, without a knowledge of them great dangers may be thrust upon an unsuspecting public. In a large city like New York, almost every known disease can be seen at one time or another and a thorough knowledge obtained of its clinical aspect and how to verify its diagnosis. It is a self-evident fact that a mistake, even on the conservative side, may become a very serious matter in alarming a whole community and it is exceedingly important that such errors should not be made. In New York, with its endless opportunities for practical research, familiarity with contagious diseases can be acquired in a comparatively short time.

Thousands of men throughout the country who are serving in the capacity of health officers will doubtless welcome this opportunity of obtaining, in a few weeks, systematic instruction in all the manifold duties that devolve upon the official guardians of the public health. The practical way of applying the latest and most approved methods of disinfection, the detection of adulteration in food, and the testing of house-plumbing must be seen and studied, by the actual or prospective health officer, to be serviceable to him. When we consider that there are in New York State alone, seventeen thousand so-called sanitarians, the great majority of whom have had no systematic laboratory, didactic or practical instruction to fit them for their vocation, the importance to the profession and to the public of

the opportunities now afforded by Cornell Medical School cannot be overestimated. Two courses will be given annually, the fall term beginning in October and continuing six weeks and the spring term beginning on the third Tuesday in May and continuing through a similar period.

ECHOES AND NEWS.

NEW YORK.

Rabies Spreading.—The New York State Health Board has instructed Dr. Thomas A. Killip, State Sanitary Physician, to visit Buffalo and all towns in western New York and report as to the epidemic of rabies which prevails in that region. This epidemic appears to be steadily creeping eastward.

Bequests to Hospitals.—By the will of Cecelia Julia Loux, the Isabelle Heimath Hospital, German Hospital, St. Francis' Hospital, St. Joseph's Hospital and the German Society each received a bequest of $3,000; Roosevelt Hospital and the New York Institution for the Blind each received $2,000 as bequests.

The City's Outdoor Poor.—The physicians for the city's outdoor poor examined 94,480 adults during 1899; 4,317 were sent to the Almshouse and 517 to the Colored Home, 862 children were sent to the Nursery and Child's Hospital and 907 to the Infants' Hospital. The sum of $67,403.71 was secured for abandoned families and for illegitimate children.

Contagious Diseases.—For the week ending March 3, 1900: Measles, 818 cases and 33 deaths; diphtheria, 262 cases and 54 deaths; laryngeal diphtheria (croup), 21 cases and 13 deaths; scarlet fever, 160 cases and 23 deaths; chicken pox, 17 cases; tuberculosis, 193 cases and 171 deaths; typhoid fever, 7 cases and 3 deaths; cerebrospinal meningitis, 7 deaths; totals, 1478 cases and 304 deaths.

Mastoiditis Prevalent.—The Manhattan Eye and Ear Hospital and the New York Eye and Ear Infirmary have had more cases of mastoiditis during the past few weeks than they have had in years before. The disease appears to prevail most in the lower part of the city and on the East Side. There were thirty-two cases at the New York Infirmary in one day. Practically all cases have required operation. In many cases grip does not appear to be a concomitant affection.

A New Hospital.—The Board of Managers of the French Benevolent Society has decided to erect a new hospital. This building and the site will cost $400,000, half of which sum has already been subscribed. The capacity of the new building will be 150 beds and 25 private rooms. This hospital is nonsectarian and makes no distinction as to nationality. The only assistance which the Society has received outside of individual subscriptions is the share allotted by the Saturday and Sunday Association. It receives no aid from the city.

The Babies' Hospital.—In the eleventh annual report of the Babies' Hospital, to October 1, 1899, the number of patients is stated to have been 394, as against 371 in 1898, and 10,165 days' treatment were furnished against 9646 for the previous year. The death-rate was lower than in 1898, over 45 per cent. of the 114 deaths being those of infants under three months of age. The summer branch of the Hospital, at Oceanic, N. J., had a prosperous season. The year's receipts were $18,494.04. There was a balance of $1322.45 on October 1, 1899.

The Gerry Society Bill.—The hot contest being waged before the Judiciary Committee of the Legislature, regarding the bill providing that the Society for the Prevention of Cruelty to Children shall no longer be exempt from State inspection, still progresses without abatement. The Governor has finally committed himself in favor of the bill, saying: "We provide for the inspection of banks and of insurance companies and surely it is as important to protect the interests of inmates of charitable institutions as it is to protect stockholders and depositors."

Garbage Disposal.—The bill before the Legislature abolishing the use of the garbage-reduction plant on Barren Island is meeting with vigorous opposition from members of the Street Cleaning Department. Street Cleaning Commissioner Nagle says that the proposed new plan would necessitate the erection in the city limits of not less than ten cremation furnaces of large capacity, of which four at least would be situated on the Island of Manhattan. It is estimated that the change from the present system of disposing of garbage would involve an outlay of over $2,000,000.

State Medical Association.—A bill was introduced in the Assembly at Albany, on February 28th, to charter the New York State Medical Association for the purpose of cultivating and advancing the science of medicine, the promotion of public health, the establishment of a death-fund for the dependents of its members, and for assisting in the work of enforcing the general medical laws of the State. The Association is authorized to hold real estate to an amount not exceeding $100,000. The governing body is to be known as a council, which will make laws for the proper government of the Association and of its branches and subordinate county associations.

Unusual Deaths.—Lawrence Akins of New Rochelle was well until March 1st, when he scratched his left thumb on a rusty nail. Soon afterward his arm began to swell and his physicians wished to amputate. He refused to have this done and died within three days from the time he received the scratch. He was 38 years old.—John Groh died on February 27th, while undergoing an operation at the Polyclinic Hos-

pital, in East Thirty-fourth street. Mr. Groh disobeyed his physician's direction to rest quietly home on the night of February 26th. Instead he went out and took stimulants freely. The operation was on the posterior nares. Cocaine was used at first, but later nitrous oxide was administered. The patient suddenly collapsed and could not be restored.

Filing of Vital Statistics.—Most of the regular practitioners and midwives of Rochester, N. Y., are plaintiffs in actions brought against the city to secure pay for registering vital statistics with the Board of Health. These bills have not been paid because it has been held by the city authorities that such payments should be made by others. A test case has already gone to the Appellate Division and has been decided in favor of the physicians. Many similar suits are pending. The constitutionality of the law governing the registration of these statistics at municipal expense is involved in these cases, and the law applies to every city in the State. The decision of the Appellate Division in the test case above noted was a unanimous affirmation of that of the lower court, and directed that the city pay the cost of the proceedings.

Obituary.—Dr. Clarence E. Beebe died on February 28th. He was fifty-one years old. He was graduated from Yale in 1871 and from the New York University Medical School in 1873. He was a member of the New York County Medical Association and of various other societies.—Dr. Christopher Prince died on March 4th, at his home in Irvington-on-Hudson. He was born in Brooklyn, in 1823. Dr. Prince studied medicine under Dr. Willard Parker and was graduated from the College of Physicians and Surgeons in his twenty-second year. He built up a very extensive practice in New York. In 1872 he was appointed police surgeon, which place he resigned to accept the surgeonship of the Fire Department. He was an active member of the Academy of Medicine, of the County Medical Society and of the Pathological Society, and was for some years chairman of the Obstetrical Section of the Academy.

PHILADELPHIA.

Health Report.—Deaths in the city for the week ending March 3rd were 596, an increase over the previous week of 151 and an increase of 30 as compared with the corresponding week of last year. Contagious diseases: Diphtheria, 106 cases, 30 deaths; scarlet fever, 70 cases, 3 deaths; typhoid fever, 66 cases, 9 deaths.

Magazine Changes Hands.—The *University Medical Magazine*, formerly published by a stock company, has recently come under the control of the Trustees of the University of Pennsylvania. Dr. C. H. Frazier has been chosen editor and the magazine will in the future be issued as the official organ of the medical department.

Pay Hospital for Contagious Diseases.—The movement toward the establishing of this hospital is assuming definite shape, the site having been selected and the erection of two pavilions, one each for diphtheria and scarlet-fever patients, will be begun shortly. Patients in the hospital will be allowed to retain the services of their own physician.

Instruction in Nursing.—A ten weeks' course for training nurses has been instituted by the Philadelphia Nurse Supply and Medical Dispensary. The purpose is to train women of all classes in the elements of nursing and to instruct young women in the practical details. Prominent society women are interested in the project. The course consists of forty evening lectures, practical demonstrations by trained nurses from the various hospitals, and actual nursing among the sick poor.

Improved Urine Separator.—At the meeting of the County Medical Society, February 28th, Dr. A. J. Downes demonstrated an instrument for "siphonage of the partitional bladder." The Harris urine separator, although giving good results in many instances, causes distress to the patient, allows a possible admixture of urines, and has a caliber larger than is needed. The instrument devised by Dr. Downes consists of two parts, a double catheter No. 13 American scale, and a partition rod. This rod has a particular shape for each sex and is longer than in the Harris instrument, the aim being to partition the whole bottom of the bladder. Separation of the urine is proven in every case.

Examination Fraud.—The report of the State Medical Board has at last been made public. The leakage of questions was traced to the State Printer's office, but efforts to discover in what manner the questions were secured have failed. Dr. D. B. Hoeh of Indiana County confessed that he supplied candidiates with questions at the June examination of 1899, but stated his inability to reveal the source, as the questions came in anonymous letters. It is stated that the college records of all but two of the men who obtained the questions indicate that they could have passed the examination on their merits, and that those two have voluntarily expressed their willingness to stand a re-examination.

The report of the State Council, submitted by the Lieutenant-Governor, states that the report of the Medical Board is practically a correct one, but that the general rules for obtaining evidence were not followed in getting at the facts, and that the statements of Dr. Hoeh are not reliable.

Academy of Surgery.—At the meeting March 5th Dr. Le Conte exhibited a patient in whom he had resected the left wrist because of tubercular arthritis. The dorsal incision between the third and fourth metacarpal bones was used. This is considered the best incision as it allows the resection of the carpus as one bone.

Dr. Shoemaker reported a case of "Interstitial Hemorrhage into the Fallopian Tube simulating

Acute Appendicitis." The patient was a woman of forty-three, married one year before. The symptoms were pain, vomiting, rigidity, and tenderness. There was no hemorrhage into the broad ligament or Douglas' cul-de-sac and no tenderness was found upon vaginal examination. Calomel was given and ice applied.. Although the pain was relieved the condition of the patient was such that operation was advised and performed thirty-two hours after the attack began. The appendix was thickened, but was not acutely inflamed. A sessile cyst was found upon the right ovary. The tube was patulous and there was no hemorrhage into the broad ligament, the rare condition of interstitial hemorrhage into the tube being present. No fetus or clot was found free in the abdomen, although ectopic gestation was suspected. The ovary and tube, also the appendix, were removed and the patient recovered.

CHICAGO.

St. Luke's Hospital.—The property of this hospital, situated on Fourteenth Street and Indiana Avenue, has been mortgaged to secure a loan of $50,000. The Directors of this institution say that the hospital has been steadily running behind because of its liberality in treating patients free of charge. The debts amount to more than $30,000.

German-American Hospital.—The officials of this hospital held their annual meeting March 1st. The reports showed that the hospital had been prosperous and that the floating debt had been wiped out. During the year 334 patients were cared for, and the income for the year amounted to $12,820.17. The expenses were $9,419.14, leaving a surplus of $3,401.03.

Statistics of Juvenile Offenders.—The collection of statistics with reference to the physical and mental condition of juvenile offenders in America, and their comparison with similar statistics compiled for the juvenile population at large, would be a valuable contribution to the sociologic information of this country. Miss Julia Lathrop, a member of the Illinois State Board of Charities, in a recent address stated that no such statistics had ever been collected in America, to her knowledge, and suggested that a useful study might be made of the condition of the boys in the Chicago Bridewell as to the points brought out in the English Industrial School investigations.

Conference of Sanitarians to Prevent the Spread of the Bubonic Plague.—Health Commissioner Reynolds has written to both Drs. Walter Wyman and George M. Sternberg suggesting the advisability of calling a national conference of sanitary officers, in April next, to consider the whole question. It is believed that a convention to discuss this one subject alone would attract universal attention and the proceedings would find the widest publicity through the daily press. The knowledge that such a convention was to be held would allay fear and the deliberations would create a sense of public security. The feeling of an impending danger that is unseen and not understood is what creates fear and panic.

Experiments in Scarlet Fever.—At a meeting of the Chicago Society of Internal Medicine, held February 27th, Dr. William K. Jaques read a paper on this subject, in which he began with the epidemics in Chicago among the poorer classes in 1897 and 1898, and which gradually spread throughout the city, lasting 1898, 1899 and 1900. He dwelt at length on the discovery of the germ of scarlatina by Dr. Wynekoop, and the announcement of the discovery of the diplococcus scarlatinæ by Dr. William J. Class. He has found the germ discovered by Dr. Class present in great numbers in the throat, in the blood, and even in the scales of scarlet fever patients. Indeed, he has found the Class diplococcus just as frequently in cases of scarlet fever as he has the Klebs-Loeffler bacillus in diphtheria.

Emergency Hospital for the Business District of Chicago.—Dr. Francis W. McNamara, in a recent article pointed out the urgent necessity for an emergency hospital located in the business district of this city for the care of emergency cases only. Chicago should erect and equip a building in its central portion, easy of access, for hospital purposes, and establish in connection an ambulance service with experienced physicians in charge who are ready at all hours to administer medical or surgical aid to the injured or sick. The remedy for this condition requires only the expenditure of a small amount of money to build a small hospital of thirty or forty beds. As the emergency cases are usually of short duration, either recovering promptly or resulting fatally in a brief time, there is no need for a larger institution.

Vital Statistics.—There were 536 deaths reported to the Chicago Health Department during the week ended February 24th. Consumption and cancer mortality were excessive, the 32 deaths from the former disease being the greatest number reported for any week in more than a year. Of the 536 deaths during the week, 105 were of children under one year of age, and 112 among those over sixty years. Deaths from pneumonia and bronchitis show a diminished number as compared with the preceding week and a marked reduction as compared with the corresponding period of 1899. Pupils to the number of 4657 were examined by the medical inspectors of schools, of which 293 were excluded because they had the evidence of contagion about them. There were 225 cases of contagious diseases reported by physicians to the Department, while 224 premises were disinfected by the Department, and 24 contagious-disease funerals were supervised. In the laboratory 132 bacteriologic examinations were made during the week; 590 tubes of vaccine lymph and 81 bottles of antitoxin were given out; 519 samples of milk and cream analyzed, of which 120 were brought to the laboratory by private individuals, and 399 were collected by the milk inspectors.

The Physicians' Club of Chicago.—At a meeting, held February 26th, the subject of "Success in Medicine" was discussed by Drs. Frank S. Johnson, E. J. Gardiner, and William E. Quine. The latter spoke of economy of time in the practice of medicine, and said that one of the best ways to economize time is to do the work in hand instantly. He knows of no better incentive to economy of time than that which is furnished by having fixed obligations, as a college engagement, a hospital engagement, or the like, making it necessary for the physician to be at a particular place at a particluar time. The ability to economize time is largely innate. He knows physicians who will fuss and stew around and be as busy in making six or ten visits a day as others would be in making from twenty-five to thirty visits. Dr. James B. Herrick discussed the subject of proper and improper advertising. Dr. Alexander Hugh Ferguson spoke of the question of fees and commissions. No physician or surgeon should charge a fee which is a hardship to a patient. A fee of ten dollars would be a hardship to a poor man, whereas a fee of ten thousand dollars would scarcely be felt by a millionaire. He characterized the practice among some physicians and surgeons of giving commissions as damnable and disreputable. In the general discussion, Drs. John E. Owens, Harold N. Moyer, Joseph Zeisler, and James E. Stubbs concurred in the statements of Dr. Ferguson.

GENERAL.

Medical Students Quarantined.—Nine students of the Detroit College of Medicine and a helper are detained in the smallpox hospital. They all had been engaged in the dissecting-room upon the body of a man who died of what was supposed to be blood-poisoning, but which finally proved to be smallpox.

Berlin Physicians Obdurate.—The proposal to admit women as members of the Berlin Medical Society has been again brought to a vote. Those who spoke in favor of their admission cited the customs of America, Switzerland and other countries, for a generation past, but to no avail, for the men by an overwhelming majority voted "no women as members."

Diphtheria Epidemic in Ithaca.—A diphtheria epidemic has been prevalent in Ithaca, New York. It is declared that the first few cases were treated lightly by the physicians and were not reported to the Board of Health. As a result no steps were taken to arrest the epidemic until very recently. The city hospital is crowded with patients, and no more can be admitted.

Bibliography of Italian Literature.—The first number of a new bibliographical bulletin of Italian medical literature is just received. *Bollettino Bibliografico delle Pubblicazioni Mediche Italiano* is its title. It is very ingeniously arranged. Articles are classified according to subject and printed in double column in the form of small cards. Such being printed on one side of the page only may be cut out, mounted on cards and thus classified. The other side is used for advertisements. In this first contribution 191 titles are thus given.

The Hahnemann Monument.—A bill granting permission for the erection of a monument in honor of Samuel Hahnemann has passed both Houses of Congress and been signed by the President. The location has not yet been selected, but a contract has been signed for the erection of the structure at a cost of $48,000, exclusive of the foundation. Subscribtions to the amount of $75,000 will be required to complete the monument with its fitting accessories and surroundings. Money is still needed. It seems to be difficult to raise money for monuments to physicians; the Rush monument fund also is still in need of additional subscriptions.

Vaccination and School Attendance.—The Supreme Court of Indiana has recently decided that an unvaccinated child may lawfully be excluded from a public school in a locality where there was danger of a smallpox epidemic, although there is no Indiana statute making vaccination compulsory, or imposing it as a condition for the privilege of attending the public schools. It was considered that the power of the local Board of Health to establish a regulation to this effect is derived from the State Board of Health, which body is authorized by an act of the Legislature to adopt rules and by-laws to prevent outbreaks and the spread of contagious and infectious diseases.

The Queen and the Wounded.—The Queen's personal interest in the men fighting the nation's battles is being constantly shown by her visits to Netley Hospital and other institutions where lie the officers and men who have been wounded in South Africa. The best illustration of her sympathy has been shown by summoning to Osborne Bugler Dunn, aged fifteen, who was the first to cross the Tugela River in a recent advance. While running with the soldiers, holding his bugle in his right hand and sounding the advance, a bullet struck his arm and the bugle fell. The boy immediately picked it up with his left hand and repeated the call. The boy's father, a sergeant, returned to the front this week, having recovered from a wound.

Sickness and Marriage Engagements.—It was decided by the Supreme Court of Appeals of Virginia, on December 7, 1899, that "a contract to marry is coupled with the implied condition that both of the parties shall remain in the enjoyment of life and health, and, if the condition of the parties has so changed that the marriage state would endanger the life or health of either, a breach of the contract is excusable. One month before the appointed date for the marriage the defendant found himself suffering from cystitis and was warned by his physician that the malady would be aggravated by marriage. He, there-

fore, broke the engagement, and suit was brought with the result above stated. Shortly after the Court of Appeals decided in his favor, the defendant married a woman other than the plaintiff.

For Psychical Research.—The Society for Psychical Research will shortly appeal to the public for $50,000 with which to investigate the phenomena of hallucinations, coincidences, apparitions, automatism, etc. Dr. James H. Hyslop, Professor of Logic at Columbia University, who is deeply interested in such work, considers that thorough and scientific investigation of these phenomena might result in a modification of the whole theory of insanity as it prevails at this time. If such investigation were made, a cure for certain forms of insanity might be discovered. "It would not apply," states Dr. Hyslop, to "acute mania, or melancholia, or to epileptic insanity, but it might apply to some forms of mental insanity which are based upon hallucinations. Many persons are put in asylums who in reality are sane and merely have psychical peculiarities."

A Reconstruction Feat.—An inquest was recently held in London upon a most singular form of "remains." An extensive fire in which several persons had narrow escapes, had occurred a few days before and among the missing was an old lady of sixty, named Forest. It was at first thought that she had taken shelter with friends, but nothing could be discovered of her whereabouts and a careful search through the ruins of the building resulted in the finding of the charred remains of a single tarsal bone. Enough of its form was preserved to admit of its identification as human and the jury after viewing the fragment and hearing the medical testimony as to its character, expressed themselves as satisfied that it was the sole remains of the unfortunate woman and accordingly returned a verdict of accidental death. This is almost equal to some of the "reconstruction" feats of paleontology.

The Plague.—The most threatening advance that the plague has made as far as our country is concerned is its appearance in the Island of Cozumel, off the coast of Yucatan. The presence of the plague at Santos in December last marked the first invasion of the Western hemisphere by that dread scourge. The invasion of Cozumel brings the disease nearer to our own borders, and is an incentive to still greater precautions on the part of our Marine Hospital Service. The decisive treatment that the plague has received in the Sandwich Islands, and the success which has attended it, is an indication of the methods that should be adopted wherever the plague makes its appearance. In view of the danger of the plague, a bill has been introduced in the New York Legislature extending the powers, in quarantine matters, of the health officer at the port of New York.

March 6th the San Francisco board of health, under the apprehension that a case of bubonic plague had been discovered there, called upon the police to put a cordon about the Chinese quarter. This was done, although definite proof of the genuineness of the case had not been presented. Cultures from the pus are now being made. The steamer "Nanyo Maru," from Japan *via* Honolulu, is held in quarantine seventy miles from Victoria, B. C., under suspicion of having the plague on board. The diagnosis rests between that and beri-beri.

Medical War News.—The triumph of the Army Medical Corps is complete. It has won, first, the admiration and praise of the intelligent public, then of Parliament, and when the situation had dawned upon the intelligence of the generals and they began to pay compliments it was thought the climax was reached. But more remained. At the inspection of the Langman Field-hospital, of which Dr. Conan Doyle is physician-in-chief, that venerable reactionary, the Duke of Cambridge, late Commander-in-Chief, actually took occasion to speak of the good work done by the Army Medical Corps as one of the bright things of the present war. When it is remembered that His Royal Highness, in the long and weary years that he was Commander-in-Chief, before, to everybody's relief, he was deftly and politely juggled out of the position, was regarded as one of the bitterest opponents of any reform of the medical service or improvement of the position of the medical officers, the magnitude of the compliment can be appreciated. It was even reported that while at the head of the army he had upon several occasions expressed himself with perfect frankness upon the absurdity of being expected to recognize medical officers as "gentlemen," in the army sense of the term at least.

Sir Wm. MacCormack sends the following interesting anecdote to the *Lancet:* Corporal Thomas (of the Worcester Regiment), Mounted Infantry, was wounded at Arundel on November 23, 1899, whilst with a party reconnoitring the hills at Arundel. He was leading his pony up a hill when a Boer, about 400 yards distant, fired at him and hit him four times. All the bullets came from the same rifle; he saw the Boer standing up to fire at him. The first bullet struck the fifth metacarpo-phalangeal joint of the right hand on the extensor surface, smashing the ends of the bones composing the joint, passing along the palmar surface of the metacarpal bones obliquely to its exit between the first and second metacarpal bone and making an irregular oval-shaped wound the largest diameter of which was three inches. The exit wound was on the extensor surface of the hand. The irregular, ragged appearance of the wound of exit was caused by smashed bones. The second bullet had its entrance in a small, round, punched-out wound, typical of the Mauser bullet, at the base of the palmar surface of the left thumb and passed obliquely upwards and outwards. Its exit was at the extensor surface of the lower extremity of the radius, the exit being irregular. The third bullet entered at the inferior angle of the left scapula, passing directly from

behind forwards. (He had turned around after being struck a second time.) The exit was at a corresponding level in front through the sixth interspace, about two inches from the median line. The track of the bullet must have been in immediate proximity to the heart, the pericardium, and the large blood-vessels. Both the entrance wound and the exit wound were small, round, regularly punched out, and typical of the Mauser bullet when striking soft structures. The fourth bullet entered behind on the left side in the tenth intercostal space, four inches from the middle line, passing through the lower part of the chest and the upper part of the abdomen. It emerged in the linea semilunaris about the level of the twelfth rib. The entrance wound and the exit wound were typical of wounds from the Mauser bullet. There were no symptoms of internal injury to either the chest or the abdomen. The patient had a slight rise of temperature for three days. I saw him sitting up in the train a few days afterwards regretting his transfer down country, his chief trouble being stiffness of his right little finger joint. The Boer who hit Corporal Thomas carried him down the hill to the relief station in his own blanket and said that he would give anything not to have shot him because he thought he was going to die.

CORRESPONDENCE.

KEELEY'S LAST MOMENTS.

To the Editor of the MEDICAL NEWS:

DEAR SIR:—I was called to attend the notorious Dr. Leslie E. Keeley just before his death. As I walked into the house he gave a few gasps and fell back dead. He was surrounded by "Christian Scientists," who had been in constant attendance for several days, treating him for an attack of the grip. I was informed that he had been under the same scientific (?) treatment for several years, being a sufferer from chronic heart disease. To all sensible people this is sufficient proof that the vaunted "Keeley Cure," from a medical aspect, is a fake pure and simple. Of course, the great bulk of the medical profession came to that conclusion years ago, but I am sure the readers of the MEDICAL NEWS will be interested to learn that one of the greatest medical fakers of our times was himself the victim of a still greater fake than his own.

West Hughes, M.D.

Los Angeles, California, March 1, 1900.

THE INTRA-UTERINE TRACTION FORCEPS.

To the Editor of the MEDICAL NEWS:

DEAR SIR:—My attention has been called by Dr. Ausgustus C. Bernays to the striking resemblance which my intra-uterine traction forceps bears to an instrument which he devised fifteen years ago.

It gives me great pleasure to acknowledge Dr. Bernays' claims to priority in devising this instrument so far as applied to intra-uterine traction. It is possible that I had seen an illustration of his instrument and forgotten it while shaping mine.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, February 24, 1900.

ANOTHER MEDICAL MEMBER OF PARLIAMENT—THE PRINCE OF WALES AND THE HOSPITALS—MR. BALFOUR AND BACTERIOLOGY—STEADY GROWTH OF CREMATION—THE HIGH DEATH-RATE OF DUBLIN—A NEW CARD GAME.

By the election of Sir Michael Foster to represent the University of London in Parliament the medical profession has secured a new representative in the legislative arena, of whom it may well be proud. Universal satisfaction is expressed with the result of the contest, which, after three days' polling on account of the scattered state of the constituency, gave the celebrated physiologist a handsome majority of over four hundred votes in a total of some two thousand five hundred. An admirable feature of the contest was its strikingly non-partisan character, as shown by the fact that the successful candidate, although a Liberal-Unionist, was nominated by the Conservatives, and, entering the field latest of all, defeated both the "regular" nominees in a hitherto strongly Liberal or Liberal-Unionist constituency. Indeed, Sir Michael frankly declined to label himself politically and his election was purely a case of the fulfilment of the pious objurgation, "and may the best man win." By a curious coincidence the last two previous holders of the seat have both resigned it on account of their elevation to the peerage, Mr. Lowe to be Viscount Sherbrook and Sir John Lubbock to be Lord Avebury, and we trust the tradition will not be broken in the case of the present incumbent. The candidate receiving the next highest number of votes, Mr. W. J. Collins, was also a member of the profession and would in many respects have made an admirable representative, but on account of his pronounced antivaccination views, medical preference was almost universally against him. Although for many years past devoted exclusively to physiology, Professor Foster was in his earlier days in active practice as a surgeon at Huntingdon.

The position of H. R. H. the Prince of Wales is rapidly becoming that of Inspector-in-General for all sorts of public organizations and is no sinecure. One day it is a new regiment, the next a hospital staff, the next a philanthropic association. Two of his functions this week have been of especial interest. One of these was the review of the entire staff of the new Yeomanry Hospital staff at Devonshire House. The medical officers headed by the Senior Surgeon, Mr. Alfred Fripp,

and Mr. Washbourne, were presented to his Highness, then followed the forty nurses, and, finally, the seventy-nine men of the hospital corps were marched into the ball-room, drawn up in line and addressed in the usual six-line official speech. The medical staff sailed the following day and the nurses and orderlies follow during the week. It seems probable that the hospital will be located at De Aar instead of near Cape Town, as at first planned.

Twenty-four hours later the Prince presided at the annual meeting of the General Council of his own Hospital Fund, which has for its purpose the supplementing of the inadequate incomes of the London hospitals. The report was a most encouraging one, as the receipts for 1899 mounted up to nearly $250,000, an increase of $45,000 over 1898. This is regarded in view of the enormous demands of the various war-funds upon the public charitable purse the past five months, as a most favorable showing. Nearly 300 disused beds have been reopened and maintained through the help of the Fund during the past three years. The claim of the Fund to be regarded as one of the war-relief group, in view of the accommodations likely to be required of the hospitals it assists for wounded and invalided soldiers, was especially urged. The Prince alluded in most complimentary terms to the absence of one of the members of the council, Sir Wm. MacCormac, whose performance of the arduous duties of active service in the field, at his time of life "reflects great credit upon him and gives the utmost satisfaction to all who know him."

At a dinner held in aid of the fund for the new Bacteriological and Physical Laboratories of Kings College, Hon. A. J. Balfour presided and made the speech of the evening. After alluding in general terms to the importance of science and scientific training as the basis of modern progress, he proceeded to express his appreciation of the prominent part in promoting not merely private but the public welfare beginning to be played by bacteriology and the results of its researches. To the English, of all people in the world, with their large tropical and subtropical empire, its value and future usefulness could hardly be over-estimated. He alluded to the fact that this had been officially recognized by the Government by the assistance extended by the Colonial Secretary, Mr. Chamberlain, to the London School of Tropical Medicine and urged his hearers to respond to the appeal of the college in a manner befitting the representatives of the wealthiest city in the world, but one which hitherto had scarcely been fully alive to her obligations to scientific research.

Public attention has twice been called to the work of the English Cremation Society within the past few months, once by the incineration at their Woking establishment of Grant Allen's remains and again a few days ago by those of the Duke of Westminister. A singular case of devotion to principle on the part of a believer in cremation is that of a British officer, killed in South Africa, whose body in accordance with his special directions was brought home all the way to Woking to be cremated. It would certainly have saved much trouble in embalming and inconvenience in transport if the cremation could have been carried out at the other end of the line. The number of cremations reported the past month is almost as large as that for the entire year of 1892.

The mortality of the Irish capital, never of the lowest, has been reaching such astounding figures of late—no less than from 35 to 50 per 100 per annum in some weeks—that it has become a public scandal, and a few weeks ago a joint committee was appointed by the Royal Colleges of Dublin, the corporation and sanitary authorities. This has just published a preliminary report, by the Sanitary Inspector, in which the safe, if not specially illuminating, conclusion is reached that the excessive death-rate is due chiefly to poverty, underfeeding, overcrowding and intemperance. If these factors will not produce a high mortality, what will? Unfortunately, they are not confined to Dublin and the commission has still the task of determining whether these elemental eliminatory agencies exist in higher degree there than elsewhere in the world, and, if so, why? As regards overcrowding, they do seem to have established some claim to excessiveness, at least to picturesqueness and ingenuity. In one room they found each of *the four corners* sublet to a separate individual or family, while the "landlord," or landlady, as it happened to be, occupied the center of the floor! No "absentee landlordism" about this arrangement or danger of rack-renting by a grasping and soulless middleman or "agent." But it really would seem as if the celebrated "pig in the parlor" principle, so charming in rural surroundings had certain draw-backs when transplanted to urban environments, and may even rise to the dignity of a special factor in the death-rate.

A most curious case of will-making under difficulties has just been before the English courts. An old lady had a stroke of paralysis with aphasia and was advised by her medical attendant, Dr. Edmunds, to make her will. The difficulty at once was how to ascertain her wishes in the matter, as there was also motor agraphia. Dr. Edmunds devised the plan of writing down the names of all her relatives upon one series of cards and the various items of her extensive property on a second series. Then the game began. Her solicitor played the title of a piece of property and the old lady after looking through her "hand" of relatives, played a name and the trick was turned and laid aside. From these "instructions" the will was drawn up and read to the testator, who nodded her assent to each item and signed the whole by making her mark. The will, of course, was disputed, but the judge declared the method pursued had been most skilful and perfectly fair, and admitted the will to probate. Dr. Edmunds is certainly to be congratulated upon the ingenuity and effectiveness of his brilliant device.

RESECTION OF GANGRENOUS INTESTINE—MURPHY'S BUTTON AND SUTURE COMPARED—GUNSHOT WOUND OF THE ABDOMEN—EXOPHTHALMOS PRODUCED BY THYROID EXTRACT—GLAUCOMA CAUSED BY HOMATROPIN—EPIPHYSEAL DISLOCATIONS.

AT the Clinical Society of London, January 26th, J. HUTCHINSON, JR., read a paper on resection of gangrenous intestine in cases of hernia, based on the records of 42 operations. There is a general impression that the use of Murphy's button has rendered resection of the intestine not only quicker but safer. To test the truth of this assumption Hutchinson made a collection of hospital cases. There were 15 examples of primary resection of intestine for gangrene performed with the Murphy button, and 16 instances in which suture alone was employed. Only one patient upon whom the button was used recovered (7 per cent.), while six patients whose intestine was sutured recovered (37 per cent.). An artificial anus without resection was performed upon 11 patients, all of whom died. This is a very striking comparison of the result of anastomosis by the button and by suture, and, moreover, the patients who died after suture lived on an average twice as long as those who were operated upon by the button. The post-mortem examination showed, too, better union of the divided ends after suture than after the use of the button. The latter is apt to cause acute congestion by its bulk, and its weight is also a disadvantage. That there is some risk of a resulting stricture after recovery is shown by post-mortem examination of patients who have lived some weeks after gastrojejunostomy has been performed. The greater time required for suture has probably been exaggerated. According to his experience the after-shock is not great. Primary resection of gangrenous, perforated or irretrievably damaged intestine in a hernia must always be attended by a high mortality, but it offers the best chance for recovery of any plan of treatment. Especial care should be taken with the mesenteric portion of the suture, and enough gut should be resected to bring the suture into healthy tissue. Maunsell's method is one of the best to follow.

A. BARKER said that he had recently resected gangrenous intestine on three occasions, using the button once and suturing twice. The patient upon whom the button was used died, and the other two recovered. He once lost a patient from paralysis of the bowel, caused by the heavy button dragging the loop of bowel into the pelvis. He, too, emphasized the necessity of resecting a sufficient amount of gut. Once he took away 35 inches, and the patient made a good recovery.

A. P. GOULD mentioned the case of a young man who was accidentally shot in the abdomen with a small revolver. There was little shock and the pain was not excessive. At operation there were found and sutured four wounds of the jejunum and two of the mesentery. The peritoneal cavity contained some blood, but no gas nor intestinal contents as far as could be seen. The patient recovered.

A. BARKER said that the amount of shock varied greatly in such cases. He once knew a man after a gunshot wound of the abdomen to walk down stairs and profess himself as feeling quite well. The velocity of the bullet must be considered. If the speed is great, the intestinal wounds will probably be small.

N. PITT said that "cow-doctors" puncture distended intestine with a trocar, and peritonitis does not follow. From this one might infer that a small bullet of high velocity may pierce the intestine and yet no serious result follow.

At the Ophthalmological Society, January 25th, W. EDMUNDS gave the results of experiments which tend to show that exophthalmos may be produced by overfeeding with thyroid extract. This is especially interesting as showing that the principal symptom of Graves' disease may be secondary to the goiter. All of his experiments were upon the lower animals, but Beclere had stated that it followed the administration of too great doses of thyroid extract for myxedema in a woman.

J. B. LAWFORD reported a case in which thyroid extract had been given with great benefit to a woman who had suffered with myxedema for five years. Four and a half years later she suffered a relapse, and was put upon thyroid extract. Exophthalmos soon developed.

G. MACKEY knew of an instance in which removal of enlarged cervical glands, and division of the cervical sympathetic, was followed by exophthalmos.

C. H. B. SHEARS read notes of a case of acute glaucoma following a single application of homatropin. A woman, aged fifty-two years, asked for reading glasses. With her hypermetropia corrected her distant vision was nearly two-thirds of normal. One or two drops of homatropin, four grains to the ounce, was put into the right eye. When she returned to the hospital one week later she had all the signs of glaucoma in that eye and could only just count fingers. Pain and vomiting and great loss of sight came on the same evening that the homatropin was used. Eserin and leeches were tried for two hours without benefit. Iridectomy was then performed and the tension and sight were quite restored in ten days and remained so up to the time of report. Shears expressed the opinion that no mydriatic should be put into the eyes of persons over thirty years of age, without careful consideration.

At the Harveian Society, February 1st, D'ARCY POWER showed a little girl whose arm had been injured in some unknown manner and kept in splints for six weeks. Four months later she came to him for a deformity at the elbow. There was a state of cubitus varus, that is to say the long axis of the arm was bent in at the elbow. All the motions of the joint were well performed.

The radiographs showed that there had been a subperiosteal separation of the lower epiphysis of the humerus, and a shifting of the whole epiphysis toward the inner side of the shaft. The external condyle of the humerus had lost its cartilaginous covering, and the internal condyle had been thickened by periosteal growth. This is an illustration of a whole class of injuries which is just beginning to be understood since they can be studied by means of the X-rays. He had advised against operation since the function of the arm was so good, although the radiograph showed that operation would not be difficult to carry out.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 1, 1900.

The President, William H. Thomson, M.D., in the Chair.

On motion of Dr. Squibb a committee was appointed to attend the meetings of the Committee on Revision of the Pharmacopœia at Washington. The members of the committee will be announced later.

Dr. Louis F. Bishop, Secretary of the Academy, read a communication asking that the Academy of Medicine formally sign a petition to Congress which is being circulated among the educational, charitable and religious institutions of the country in order to secure a remission of the present exorbitant war-tax on bequests. According to the present law ten per cent. of all moneys devised to such institutions goes to the General Government. As this entails a large loss of money to institutions whch are intended only for the public good, and as the Government is now in no pressing need of funds, it is hoped that an amendatory clause will be enacted to do away with this tax. On motion the President of the Academy was empowered to formally sign the petition drawn up for this purpose.

A communication was read from Dr. W. W. Keen, President of the American Medical Association, asking that the New York Academy of Medicine take official action as to Senator Gallinger's bill for the limitation of vivisection in the District of Columbia, which has been introduced into the present Congress. The President, Dr. Thomson, suggested that not only should the formal expression of the opinion of the Academy of Medicine with regard to this bill be sent to Washington, but that at the proper time a committee, selected for the purpose, should be sent to appear before the Legislative Committee and do all in their power to show that the enactment of this bill, which is being presented so persistently at each succeeding session of Congress, is calculated to do great harm to the development of scientific medicine in America. On motion the formal disapproval by the Academy of Senator Gallinger's bill was directed to be expressed in writing.

Diseases of the Heart.—The discussion which had been opened up by Dr. Musser's paper on myocarditis and Dr. Koplik's paper on myocarditis in children at the last meeting, was resumed.

Dr. Morris Manges said that to know the causes of the failure of compensation is very often to be in a position to treat heart failure at the serious moments when digitalis and other heart tonics fail. Romberg of Leipzig carefully studied a large series of cases and found that the average duration of compensation was seven years, and this in spite of the fact that in one-third of the cases proper compensation was never established. In one patient compensation endured for fifty-three years. We are in the midst of a transition period. Leyden of Berlin by his recent work on the nervous mechanism of the heart and the autonomy of the heart muscle has brought out a number of facts important to practitioners and very different from the old ideas that used to be taught in physiology. The important point in the establishment and continuance of heart compensation is the myocardium. It used to be thought that undue distention of the heart gave rise to fatty degeneration. Fatty degeneration of the heart muscle is now considered to be of minor importance. Residual blood in the ventricle and auricle is not so important as it was formerly thought to be. Where the heart muscle is reasonably healthy undue distention will return. Where nutrition is unequal to the importunity, however, the heart muscle will surely fail. Hypertrophy of the muscular fibers does something to overcome pathological conditions, but there must be a return to normal nutrition or compensation will not be established. For this the tone of the heart muscle is important.

Heart Dilatation and Its Results.—Dr. Theodore Schott of Nauheim showed by a series of skiagraphs that the heart is distinctly dilated after severe exercise, such as bicycling, running, and the like. This dilatation of the heart, if associated with malnutrition of the muscle, may become permanent Dr. Krehl showed that all changes in the blood vessels of the heart began in an endo- or pericarditis which caused muscle necrosis and fatty degeneration. This occurs at various points throughout the organ. Dehio showed that fibrosis was not an uncommon process in the heart. This consists of a development of fibrous tissue in the midst of the muscle fibers and is really a conservative process on nature's part. When the muscle fibers have lost some of their elasticity because of the occurrence of degeneration the elasticity of the connective tissue supplies its place to a certain extent. The foci of degeneration occur by preference in the left auricle, the left ventricle, the right ventricle and in the right auricle respectively.

Importance of Myocarditis.—Where endocarditis develops in a heart the prognosis depends not so much on the endocarditis as on the complicating myocarditis. The hypertrophy which oc-

curs as a consequence of both these inflammations is followed by subsequent changes in the myocardium mainly connected with the blood vessels, thus altering the nutrition of the organ. Myocarditic changes may be conservative for a time, preventing overaction of the heart. When arteriosclerosis sets in, however, degeneration is apt to occur although with proper care it may be controlled for a long time. It is the custom to talk so much of compensation by itself and without reference to its causes that it is apt to be considered as a definite entity. It is not, however, but is only a condition of equilibrium induced by favorable circumstances in a heart weakened by some affection. The easiest way to understand this is to study the factors which may undo the equilibrium. Such factors are generally unfavorable constitutional conditions, such as anemia with its consequent effect on the nutrition of the heart muscle. Obesity has a like effect. Decomposition often follows reduction cures. To undertake the reduction of very much weight in a person whose heart is already enfeebled is to run the risk of seriously injuring, perhaps permanently, the compensation. From Carlsbad the physicians are now accustomed to send patients who have taken the reduction cure to Nauheim for after-treatment. It is no wonder that this is so, for rapid loss of flesh always means loss of tone in all muscles, especially the heart muscle. Organic disease, such as nephritis, or the constitutional diseases like diabetes or gout impair the nutrition of the heart muscle and so lead to decompensation. The specific infections, as influenza, have a toxic effect upon the heart. Rheumatism is especially liable to affect the heart in a number of ways. It not only damages the valves, but may directly affect the myocardia. Many of the toxins of the infectious fevers affect the vasomotor system and so disturb the local nutrition. Coronary arteriosclerosis may set in and then the patient must be warned to avoid any overexertion or strain of the heart muscles.

Muscular Overexertion.—This is an important factor in causing the development of decompensation. Athletes frequently strain the muscular fibers of their hearts. Bicycling in our day has become a serious disturber of heart compensation. Schroetter of Vienna insists that exercise must be taken with the head as well as with the muscles. That is it must be above all judicious. Parturition is apt to act as a strain on the heart muscle as does overexertion in athletics. Pericardial adhesions hamper the heart muscle very much. These lead to premature degeneration. Chronic lung troubles are another important source of decompensation. Krehl has shown that the degeneration of the heart muscle begins very often in the right auricle. Nervous conditions of the heart not necessarily connected with any organic lesions may also lead to premature degeneration. Extreme mental emotion, anxiety, fright, worry, all may have this effect. A broken heart is an actuality. The influence of extreme grief is sufficient to cause degeneration which prevents heart action. Osler considers that acute dilatation from such causes may be followed by death in a few days or may lead to dropsy and chronic cardiac weakness.

Abuse of Drugs.—Unsuitable medication is a frequent source of cardiac decomposition. Cardiac tonics especially are open to abuse. To consider heart murmurs as a signal for the use of digitalis or strophanthus or some allied drug is to precipitate cardiac failure. The Nauheim treatment and Zander apparatus are often abused in a way that leads to serious disturbance of a compensation which might otherwise have kept the patient in reasonably good condition for years. Such cases have even occurred at Nauheim itself, and patients have been worse on their return from a voyage that they hoped would be a source of the greatest good. The coal-tar products have also been abused in the same way and with the same serious consequences. Thyroid preparations have been liable to the same abuse. Cardiac treatment should not be begun merely because murmurs are heard, no matter what the character of the murmurs may be. Only when some signs of heart failure are present should active heart treatment be instituted. It must be remembered that constitutional treatment is at least as important as direct treatment of the heart itself.

Aortic Valvulitis.—Dr. Frank W. Jackson said that the prominent causes of chronic aortic valvulitis, which are the only cases he cared to consider, are rheumatism, syphilis, alcohol and gout. In our time there is no doubt that we have good reason to think that a very important cause of aortic valvular disease is muscular strain. Athletes and those who overexert themselves are especially liable to this disorder. Of the two forms of aortic trouble, pure aortic stenosis is rare although it is the usual form that aortic trouble takes in the aged. It may lead to disturbances of the cerebral circulation and cause fainting or give rise to emboli. It must be remembered that a systolic murmur at the base of the heart does not necessarily imply an aortic stenosis. It may mean only an aortitis or only a thickening of the aortic valve and may occur under certain conditions in health. Aortic insufficiency is as common as aortic stenosis is rare. A combination of the two is not as common as is sometimes considered. A double murmur may exist at the aortic cartilage and yet the only heart lesion be a simple aortic regurgitation. Osler thinks that 30 to 50 per cent. of all valvulitis terminates in aortic insufficiency. Overexertion is a very common cause and the athlete's heart is typically that of aortic insufficiency. The symptoms are characteristic. Too much weight has been given to the murmur. In the absence of all murmur there may still be an aortic insufficiency. The murmur may be evanescent. It may disappear for a day or two, or even an hour or two and then return. Usually such a varying murmur is functional in origin, but it must be borne in mind that it can be organic. The murmur may be inaudible to the ear and be plainly heard by the stethoscope. It may be ab-

solutely inaudible by the stethoscope and yet be plainly heard by the ear. For this fact there is no explanation.

Regurgitant Murmur.—The murmur of aortic regurgitation may not always be heard best in the classical place. It may at times be best heard at the ensiform cartilage or at the base of the heart; disappear when the ear is carried down the sternum, and yet be plainly heard at the end of the sternum. Prof. Allbutt's picturesque expression of this fact is worth recalling, "Murmurs, like rivers, sometimes run under ground." The murmur of an aortic regurgitation may be heard only at the apex, and give rise to the thought that a mitral lesion exists. In a word the murmur as a symptom requires careful corroboration. A harsh systolic murmur at the second left intercostal cartilage may be due to aortic valvulitis, but may also be due to pressure on the pulmonary artery or to anemia. The size of the heart is very important in aortic regurgitation. The form of the thorax may give the impression of an enlarged heart when no enlargement exists. In a long thin thorax a large part of the heart is uncovered in front and so a normal organ may simulate the heaving impulse of a hypertrophied heart. It may also give the impression of an apex beat in the sixth interspace when it is really in the fifth. It must be borne in mind also that tumultuous heart action may mean no more than a neurosis of the heart. The condition of the kidneys should always be looked to very carefully, for an enlargement due to nephritis may closely simulate aortic disease. Pain is an especial symptom of both forms of aortic disease. In cases in which the symptoms of pain was particularly investigated sixty-eight per cent. of those suffering from aortic trouble complained of it. In 180 cases of mitral valvulitis only seven and two-thirds per cent. complained of pain.

Aortitis Angina.—Inflammation of aorta may exist either with or without aortic valvular trouble. It is usually a chronic productive inflammation leading to necrosis and degeneration with production of atheromatous plates in the aorta, or it blocks the orifices of the coronary arteries, or leads to aneurism. The rough surface of the aorta over the inflamed part may give rise to a distinct murmur. Arteriosclerosis of the coronary arteries is much more frequent in New York than it is usually thought to be. The symptoms it occasions are usually attributed to dyspepsia. When a frank attack of angina pectoris occurs it is hard to understand how many practitioners still cling to the idea that there may be nothing more serious the matter than some functional stomach trouble. In a recent case the patient said he felt as if a devil were under his breastbone. There was no murmur although the aortic sound was weak. The patient died in a typical attack of angina. In another case in which a man had been denied insurance because his pulse was constantly 90 and occasionally intermitted there had been some pains in the heart region and down the arm. Murmurs were absent and there were very few signs of heart trouble. The patient died, however, from angina, having his first characteristic attack at the end of life. Usually in these cases there is enlargement, and the aortic sounds are feeble or absent. In addition to this, changes can be noted in the arteries in other parts of the body.

Dr. Thomas E. Satterthwaite's paper, entitled "Recent Methods of Treatment of Heart Diseases by Baths and Exercises," was then read (see p. 361).

The Myocardium in Compensation.—In the discussion Dr. Leonard Weber said that the important factor with regard to loss of compensation is the degeneration of the myocardium. If the myocardium is not diseased the heart muscle may be overstretched and yet recover. This has occurred in his own personal experience. If this were not true there would be many more deaths from acute rheumatism. It is true the overstretching can cause a fatal issue by its suddenness, heart failure setting in as a consequence of the continued weakness of the circulation. One of the difficulties in discussing the older literature is that the existence or non-existence of degeneration was determined on autopsy by macroscopical examination alone. At the present time microscopic examination discloses extensive degeneration when there is not the slightest sign of degeneration to the naked eye. Usually there are a number of foci in process of degeneration scattered here and there, especially at certain susceptible points in the heart muscle. Of late years there has been a good deal of talk in America of Nauheim and of the Nauheim methods of treatment. It seems of interest then to give a few "don'ts" from the experience of one who has been at Nauheim and who has seen the results of mistakes made by practitioners in sending patients to Nauheim. (1) Don't send neurasthenic patients. When patients have begun to lose their personal grip of themselves and are morbidly introspective they should not be sent to Nauheim, but to the bracing air of the mountains. (2) Don't send patients immediately after acute rheumatism. Nauheim itself is damp and eminently unfavorable for this class of patients and the baths do them more harm than good. At Nauheim it is the custom to say that the baths bring the rheumatism out, but it is really the climate of the place. (3) Don't send patients with tabes, nor as a rule patients suffering from incurable nervous affections, even though they may have complicating heart affections. Such patients may be afforded temporary relief by the indifferent thermal baths of other watering-places. (4) Don't fail to provide your patient with an accurate written history containing the exact diagnosis of his ailment, of any complications that may exist and of a list of the prescriptions that he has been taking recently. During the season physicians at Nauheim are extremely busy. The season lasts but a few months in the summertime and the doctors must make their living for the year. They may not make exact diagnoses,

and thus may miss important complications that contraindicate certain features of the treatment. (5) Don't, if you are giving Nauheim treatment at home, advise baths every day, but at most every other day, and only as frequently as that for sthenic cases. Ever fourth day is sufficient for the ordinary weak hearts that are the most suitable subjects for this treatment.

Heart Murmurs.—Dr. William H. Thomson said that he had arranged this discussion on diseases of the heart mainly with the idea of bringing out the fact that murmurs are not the all important symptoms in cardiac affections. There are a number of symptoms that have great significance apart from murmurs. Dr. Musser showed how insidious may be the progress of myocarditis and how it must be missed very frequently even when a good deal of care is taken in the examination of the patient. These cases terminate very frequently in congestion of the lungs. A not unusual symptom is rather rapid short breathing with comparatively long inspiration. An alteration in the complexion is not infrequent although it is not invariably present. A weak heart impulse and a weak pulse are strongly confirmative of other symptoms that may be present. Mental and renal symptoms sometimes supervene and help to substantiate the diagnosis. Dr. Koplik showed the importance of the myocardium in children. Very often this becomes degenerated during one of the exanthemata in early life or from the violent coughing of whooping-cough and then, when one of the infectious fevers develops later, heart failure is apt to supervene. A study of heart diseases shows that the heart is very different from an organ that merely opens and shuts valves. The muscular walls of the heart itself are much more important than the valvular mechanism. Defects of the valvular mechanism may be made up for, but the degeneration of the heart muscles cannot. It is a great mistake of therapeutics to place much reliance on the heart tonics in the hope of deriving from them any permanent relief. Digitalis, strophanthus, and nitroglycerin only stimulate function for the time being, but if relied on for any length of time inevitably lead to disappointment. They are only adjuvants to the real heart remedies. These are open air exercise, good hygiene, plenteous unirritating food, everything, in a word, that puts the patient in a good condition. Some time we shall have open air sanatoria for heart diseases. Then we will have the true rational treatment for cardiac affections. All muscular power is in direct proportion to the respiration. This is a great biological principle. If we breathed through our skins as does the flea we should be able to leap as he does. The difference between our comparative muscular powers is due to the greater amount of oxygen the little creature absorbs. It is wonderful what an effect open air treatment has on the heart, just in the same way it affects all muscles. A camping tour for five or six weeks will do more for failure of muscular power in the bladder than almost anything else that can be advised. Gynecologists could go out of business if the doctrine of fresh air for women were more persistently practised.

As to drugs, iron is important because it helps us to breathe. It is the iron compounds in the blood that act as carriers of oxygen. Next to iron the saline purgatives are the best drugs. These relieve the congested circulation and so do a great deal of good. The saline waters of Kissingen and Vichy are of exactly the same formula as the blood, minus the corpuscular elements. There is no stimulant that equals a full dose of these for hepatic torpor and chronic congestive conditions during cardiac affections. The intermittent use of calomel is an extremely important and helpful therapeutic measure. Sodium iodide often does a great deal of good for the relief of symptoms. Undoubtedly the judicious use of these drugs helps to prolong life.

NEW YORK COUNTY MEDICAL SOCIETY.

Stated Meeting, Held Monday, January 29, 1900.

The President, George B. Fowler, M.D., in the Chair.

Dr. Fowler announced that owing to the praiseworthy efforts of Dr. Henry Dwight Chapin, the Chairman of the Committee on Hygiene of the New York County Medical Society, the members of the Society would have the opportunity of listening to a thorough discussion of New York's milk supply, its character, its sources, its safeguards, its dangers, of the remedies that would be used to improve it and the methods that could be employed to gradually make it the best milk supply in the world.

New York's Milk Supply.—Dr. Chapin said that there was no subject more important for physicians and for the general public in the matter of food supply than the milk furnished to New York. In all 1,250,000 quarts are delivered in New York every day. This comes from five States, *viz.*, Connecticut, Massachusetts, New Jersey, Pennsylvania, and New York. In the city of New York there are 23,500 cows. Most of the milk that is supplied is at least twelve hours old and a great deal of it from twenty-four to thirty-six hours old. It is easy to understand how difficult it is to keep milk clean and how important it is that it should originally be obtained as free from foreign matter as possible. In many places where milk is shipped there are separating stations where by centrifugation foreign particles are removed. At one of these stations 1800 quarts are purified in about two hours. The examination of the sediment shows that it contains air, pus, blood, cocci, bacilli, and an amount of vegetable matter partly from hay and straw in the stables, and partly from the excrement of the animal. The solution of the problem of pure milk is cleanliness on the farm. If this lesson can be taught great good would

be accomplished. It can only be taught, however, by making the farmer appreciate that greater cleanliness means an increased price for his milk. At present in spite of stringent laws on the subject there is a large sale of various preservatives of milk. These are extensively advertised by most of the sellers of dairy articles. The most commonly used preservatives are boric acid, borax and formalin. None of them are harmless and formalin, especially, hardens the curd and makes it very difficult of digestion. It is interesting in this regard to note that a substance has recently been placed on the English market which is called lactohorn. It is meant to replace horn gutta-percha, ivory and celluloid for knife-handles, combs, and the like. It is made from the caseine of cow's milk hardened by means of formaldehyde. Physicians can improve the present condition with regard to the milk supply by united action. An advisory board of physicians who would study the conditions and advise both farmer and dealer would be of the greatest value. A physician advisor has been appointed to a number of private dairies and this feature has led to some very notable improvements and has been a source of a great deal of satisfaction even from a business point of view.

Department of Agriculture and Milk.—Major Henry E. Alvard discussed the dairy division of the Bureau of Animal Industry at Washington, of which he is chief, and its connection with the dairy industry in the United States. Up to the present time there has been no surplus of dairy products in the United States except of cheese, and therefore it has not been necessary to look for foreign markets. At the present time, however, there are indications that there will be a surplus of dairy products. It is of the greatest interest that our dairy products should be of the very best quality and an exhibit in this department is planned for the exposition at Paris. At present the statistics of the milk supply are very incomplete. The last census gives about one cow to every fourteen inhabitants of the United States. This seems a reasonable number, but a little consideration will show that it is inadequate to supply the amount of milk that should be used. The average cow is supposed to yield daily from six to eight quarts, but in reality gives less than four quarts, so that there is scarcely more than half a pint of milk a day to each inhabitant of the country. The conditions for the collection and distribution of milk in the cities of the United States have improved very much during the last twenty years. Not only is the milk itself better, being richer in fats and solids, but it is more free from organic material of all kind, especially micro-organisms. Alarmist reports of the possibility of the spread of disease by means of milk do much harm. Occasionally, but, it must be said, very rarely do they serve to prevent some few cases of disease. The average amount of cream on the milk generally supplied to cities is four per cent., although only three per cent. as a rule is required by law. It is very probable that four per cent. milk would prove almost too rich and would require dilution for infants and for invalids. Preservatives, boric acid, formalin and the like, are rightly condemned. They put a veil over evil and set a premium on uncleanliness. Sterilization and Pasteurization, although it is the custom to laud them so much in our day, are scarcely better. At best they are only a cooking of the milk, cover a multitude of sins in its preparation, and put a premium on carelessness. While in particular cases for infants and invalids they may be of use, their employment should never become a general rule. Condensed milk is much less digestible than is plain whole milk. This entire subject needs the most careful consideration.

Value of Skim-milk.—There is in this country an immense supply of a most valuable food product which is not made use of to the extent to which it ought to be. Skim-milk is not permitted to enter the city of New York, although immense quantities of it are easily accessible. The method of dealing with the subject can only be characterized as the lazy man's way and a criminal way. The sale of skim-milk might easily be regulated, although this, of course, would require care and the proper enforcement of laws. Absolute prohibition seems more easy to the authorities, but it is not so effective in the end. As a matter of fact no animal food compares pound for pound with skim-milk in its value as a food product. Yet this very valuable substance is absolutely forbidden in New York City. It may not even be sold for what it is. While other towns throughout the country derive a very great advantage from it and use it at two to three cents a quart, New Yorkers are absolutely precluded from its use. A cheap, wholesome food, readily accessible, is thus entirely denied to the poor. At the same time condensed skim-milk may be purchased in the open market. There is no question in regard to the better and well-known brands in which the whole milk is used for condensing purposes, but of condensed milk at five, six, and eight cents a pound; fifteen to eighteen cents a pound must be the price if there is to be any guarantee that it is whole milk which has been condensed. This treatment of the skim-milk question constitutes an unfortunate blot on New York's management of her milk supply which should be removed as soon as possible. It will not be hard to do it and the reform will be of great advantage to the poor and will supply them with most nutritious material for food at the very lowest rates.

Bacteria in Milk.—Professor H. W. Conn of Wesleyan University, Middletown, Conn., reviewed the recent advances in the bacteriology of milk. He agrees with Major Alvord that alarmists on the subject of danger from infected milk are liable to do a great deal more harm than good. Just what are the noxious elements which may get into the milk it is well to know and to provide against. If the sediment from an ordinary separator be examined it will be found to contain sticks, insects, legs and wings, particles of hay and straw, blood, pus, all kinds of dust and quite

an amount of organic material. Most of this organic material is really composed of cow excrement. It has been calculated that three hundred pounds of bovine excrement find their way into New York City every day in the milk. The reason for this is very clear. The cows in most dairies are never cleaned. The excrement is allowed to cake on them until thoroughly dried, when it is easily rubbed off during the milking process. Much of this may be removed by the separator. But unfortunately the separator is entirely unable to remove the finer particles. As a matter of fact, more bacteria can be found after the passage of the milk through the separator than before. All that seems to be accomplished by centrifugation is that hosts of bacteria clinging together around particles of dust are broken up and diffused more widely through the milk. It is important to know just where the bacteria come from that get into the milk. Their first source is from the dirty hands of the milker. The second source is the air. Very often when cows are being fed, hay is shaken down before them and the animal while feeding shakes this up more or less. This gives rise to a cloud of dust-particles to most of which a number of bacteria cling. The third source is the vessel in which the milk is placed. These vessels are either never thoroughly washed or are washed with unclean water. Even after thorough cleansing they are allowed to remain exposed to dusty air. The fourth and most important source of bacteria is the cow herself. There are no bacteria in the milk when it is secreted from the gland, but there is always a number of bacteria in the milk-duct which accumulate between the milkings, which are washed out by the first milk that is pressed from the udder. It has been shown by demonstration that there is a constant rain of bacteria beneath the animal. Gelatine plates exposed for a short time beneath the animal show a large number of colonies.

Danger from Milk Bacteria.—Most of the bacteria in milk are practically innocuous. In fact, even in so-called pure milk from three to four thousand will be found in every cubic inch. In ordinary city milk three to six million bacteria per cubic inch is not an unusual number. It is only when the number reaches three to four hundred millions per cubic centimeter that the milk is considered to be very bad. The number of bacteria in any given sample of milk depends, first, on the cleanness of the dairy from which it has come and, secondly, on the age of the milk and the temperature at which it has been kept since it came from the animal. London derives all of its milk supply from a radius of 80 miles and the average age of the milk when distributed is about seven hours. Berlin derives its milk supply from a radius of thirty miles only and practically none of it is more than six hours old when distributed. New York, as has been told this evening, derives its milk supply from a radius of over 300 miles and yet because ice is freely used during its transportation the bacteria are not so numerous in the average sample of the city's milk as in an average sample of that supplied to London or Berlin. Milk is eminently liable to be affected by micro-organisms, yet this fact is not entirely a disadvantage. It is to it that we owe the milk industry. If the grocer could store and sell milk as he does molasses there would be practically an end to the immense industry which has grown up to supply our large cities with milk. Were we to blot out the bacteria there would be other disadvantages in addition to those that would accrue to the present milk trade. The flavor of butter is mainly due to bacteria. In this country we are prejudiced in favor of rather highly flavored butter. In Europe a tasteless butter is preferred, but such dairy products would not be popular in this country. With regard to cheese nearly the same thing is true. Practically all the varieties of cheese are due to different varieties of microbes that grow in the curd and produce the flavors which are so gratifying to the taste. It must be borne in mind, then, that most of the microbes in milk are absolutely harmless. Many of them are very beneficial.

Disease Producers in Milk.—Three types of disease-producing materials are found in milk; first, that from disease of the cow herself; secondly, that due to contamination of the milk after it has come from the animal and, third, that due to toxins produced by bacteria which grow in the milk. Of the first type of disease-producers the most prominent is the tubercle bacillus. No doubt there exists in milch cows considerable tuberculosis. There is also no doubt that a tuberculous cow may give tuberculous milk. Where the tuberculous process exists in the udder of the cow there will almost always be tubercle bacilli in the milk. It is extremely uncertain whether tubercle bacilli ever get into the milk when the tuberculous processes are situated in other parts of the animal than in the lacteal apparatus. Granting the presence of tubercle bacilli in milk it is still uncertain whether the tubercle bacilli which produce tuberculosis in cattle will also produce the disease in human beings. How much risk there may be is not certain. Some slight amount of danger exists, but there is danger in everything in this world and the risk of being infected with tuberculosis by tuberculous milk is certainly much less than was formerly thought.

Tuberculosis in a large majority of cases first attacks the lungs. It obtains entrance by the breath, not by the food. Intestinal tuberculosis as a primary infection is rare. It is at least possible that the bacillus which produces tuberculosis in the cow is not pathogenic for man and that the bacillus of human tuberculosis may not affect the cow.

Human Tuberculosis Decreasing.—While human tuberculosis is on the decrease, bovine tuberculosis is on the increase. Human tuberculosis is decreasing as rapidly in England and the United States as it is in Germany, although in the English-speaking countries milk is used raw, while on the Continent it is always boiled before being taken. There is probably greater danger

in an evening at the theatre or at the opera than there is in the ordinary consumption of unboiled milk. It is probably that at such gatherings infection most frequently occurs.

Scarlet fever and diphtheria are perhaps communicated through milk. Certain reported epidemics in England seem to prove this, although as yet here in America we have had no observations confirming this fact. The most important secondary contamination to which milk is liable is that with the typhoid bacillus. There are reports now in medical literature of more than fifty epidemics of typhoid fever traceably to the milk supply. The great reason why typhoid fever is so much more apt to be communicated by milk than is tuberculosis is that the typhoid bacillus grows in milk, while the tubercle bacillus does not. In these epidemics the typhoid fever can be traced all along a milkman's route. It is an interesting and important observation that as yet there has been no instance in large cities of a typhoid fever epidemic being traced to the milk supply. The sporadic cases which occur in large cities may be due to the milk supply, but the milk is usually so mixed from different sources that it is impossible to decide just where the infection may have come from. In addition to typhoid fever there are a series of intestinal diseases especially marked by diarrhea which occurs as the result of the bacteria in milk. These do not seem to be due to any particular germ, nor to any single pathological entity, but are the result of the slow poisoning consequent on the constant presence of bacterial toxins in the milk for considerable periods. That this is the true explanation of the etiology of these diseases may be seen from the fact that the virulence of the epidemic rises and falls with the temperature and the whole number of bacteria present in the milk, while no definite pathologic germ can be found.

Remedy for Present Condition.—The ideal remedy for the present abuses and dangers in the milk supply would be absolute cleanliness in the dairy and on the farm. This does not, however, seem to be possible in the present stage of civilization. In the words of an old friend "it is a condition and not a theory" that is present. The actual condition must be met as far as possible. There is no doubt that Pasteurization of milk covers up a multitude of evils. But it undoubtedly constitutes the best method at present for treating the contaminated milk. At Copenhagen there is a large establishment in which milk is Pasteurized and sold at the same price as ordinary milk. The reason very candidly given for this being done is that less care is needed in the collection of milk which is to be Pasteurized. Under these circumstances, of course, Pasteurization is rather an evil than a good. Where children must be fed with milk long hours after its collection there is no doubt that Pasteurization will prevent many of the dangers to which they would otherwise be exposed. For invalids and weaklings generally the doctor will, of course, prefer the milk Pasteurized; it will still contain noxious substances, for not all of the toxins of the bacteria that are present in the milk are destroyed, but at least all the living germs have been killed and infections will not take place.

Cheap Milk is Poor Milk.—There is the cardinal principle that must be remembered when buying milk for family use. If a proper price is not paid for milk the purchaser cannot expect to get a good product. Milk constitutes one of the most valuable food products that we have. It should be used much more than it is, but if it is to be used with benefit and without danger the consumer must be satisfied to pay a fair price for it.

Dr. Herman Betz, in charge of the inspection of milk, Department of Health, New York City, read a paper entitled "The Work of the New York Board of Health in the Inspection of Milk."

Milk-Dealer's Standpoint.—Mr. Cuddebach read a paper on this subject, in which he said: There are two classes of purchasers of milk, those who want cheap milk, and those who want good milk irrespective of the cost. The standard as to what constitutes good milk is very vague in most people's mind. There was a time not very remote when people thought that good milk should give ten per cent. of cream. This led ingenious unscrupulous dealers to remove a certain amount of the skim-milk underneath the cream and thus spoil the correct proportion of the natural milk. Of late years the centrifuge has been found a very useful machine in removing dirt of various kinds from the milk. It has been found by the dealer, however, that the use of the centrifugal separator so disturbs the cream in the milk that it does not rise to the top as plentifully as it did before. This spoils the milk in some people's eyes and often hurts the sale. Thus a process which benefits the milk the dealers find to be a positive disadvantage. It is evident then that an education of the people is needed which will enable them to appreciate good milk. The law of supply and demand will inevitably be exerted. The dealer will not supply a less salable product and is perfectly ready to make any changes which will benefit his trade. If the people demand thick cream at the top of the milk with plenty of dirt at the bottom of the bottle, that is what they have to provide. If there were a good demand for good milk there would need to be no increase of price to supply it.

Mr. L. B. Halsey said that this is the first time that doctors and milk dealers have gotten together to exchange ideas on this important topic of the milk supply of a great city. Not all milk dealers are in the business merely for all the money that can possibly be made out of it. Many of them are ready to make some sacrifices to raise the standard of the product which they are handling. There is no doubt that proper rewards will come to those who make some present sacrifices for the purpose of securing a better product for distribution. Milk cans must be made sterile as far as elbow grease, hot water and soap and soda with plenty of sunlight can make them. To have the farmer cleanly, however, we must assure him a

fair price for his milk. We cannot go and demand extra precautions and offer him no more than he can get by his present careless methods. To get good milk and distribute it at less than eight cents a quart is impossible. To buy milk at a less price than this is to encourage the furnishing of a bad product. The people must be educated to know what good milk means. Even physicians may need some instructions in the matter. It is almost amusing to consider how the milk supply of wealthy families is obtained at the present moment. The buying of milk is left to the chef. He, of course, does not buy what he knows to be the best milk, but obtains his supply from the man who will pay him a commission of ten, fifteen, or twenty per cent. Practically, then, the milk-dealer may supply him with whatever sort of milk he cares to and no complaint will be heard. The milk-dealer, then, cannot look to the multimillionaire families for any encouragement in providing good milk. If the woman of the house is entirely engaged with society occupations and women's clubs and her charities, she cannot see to the milk supply and that duty devolves on the cook. If you want to sell milk to the cook you must "do the right thing by her" and then you can sell her what milk you please. Price, not quality, is the desideratum. It is evident, then, that a good deal of education is needed among all classes of society in order that good milk may be appreciated. For this education of the classes the milk-dealer must look to the physician. Working together good milk supply can be secured if the public is satisfied to pay a fair price for a good product.

In discussion Dr. Betz said, with regard to certain assertions made by Major Alvord that a word must be said in extenuation of the regulations with regard to skimmed milk in New York. No skimmed condensed milk is allowed to be sold. Brand after brand has been driven from the market. It may be said that at the present time there is practically no sale of it in the city. The use of preservatives has also been entirely driven out. For years now although frequent samples have been tested in the laboratory for the presence of preservatives none have been found. Some years ago formaldehyde was found in certain samples of milk, but it is no longer used.

Human Tuberculosis Contagious for Cattle.—The question has been raised whether the tubercle bacilli from human subjects are ever pathogenic for animals and the converse as to whether animal tubercle bacilli are pathogenic for man. A very striking illustration of the first occurred not long ago in the service of the New York City Board of Health. There is a sanatorium for tuberculous patients within the city limits situated on Long Island Sound. Belonging to the sanatorium there was a herd of five cows. Tuberculosis was suspected to exist among the animals and a test showed that four out of the five were tuberculous. The fifth animal gave absolutely no reaction to the tuberculin test. Three months later, however, the tuberculin test proved positive. The animals were all killed and proved to be extensively tuberculous. It was then noted that the animals were accustomed to feed on a lawn where the tuberculous patients frequently used to sit. Undoubtedly the sputum from these patients on the grass was the source of the disease in the cattle. It seems worth while to report a slight epidemic of typhoid fever that occurred from milk in New York, since it has been said that it is hard to trace such epidemics, as a rule, in large cities, and none have been reported. A series of cases of typhoid fever occurred in a fashionable boarding-school on the west side of the city. After careful investigation nothing suspicious could be found in the house itself, in the inmates or the water supply. It was, however, deemed advisable to trace the milk supply. This came from a dairy out on the Sussex road in New Jersey. Investigation showed that here was the source of the epidemic. A farmer's son had been treated for typhoid malaria. The stools had been thrown into a privy situated on a stream above the dairy. While this water was not used for washing the cans it was used for cooling them and in this way the typhoid bacilli got into the milk. As a the result of the same source of infection a number of towns in New Jersey had epidemics of typhoid plainly traceable to the milk supply.

Failure of Health Board.—Dr. Piffard said that instead of improving the milk supply the improper and unwise regulations of the Health Board have proved a source of harm. There has been no improvement in the regulations for fifteen years. The milk supply has undoubtedly become better, but for this the health authorities must not be thanked, but the truly commercial spirit of the milk-dealers who realize that a good product is more profitable in the end. Three per cent. of cream is entirely too low a standard for milk. It should be four per cent. at least. Other milks of even higher cream standards should be sold with the guarantee of their richness. The test of three per cent. of cream and twelve per cent. of solids in milk is entirely a false standard. The farmers in Delaware county found that when they shipped four hundred gallons of milk with four per cent. of cream on it they got no more for it than if it had but three per cent. of cream. They therefore skimmed forty gallons of the milk, removing the cream and putting the skimmed milk back, thus making the milk of the proper standard as regards cream and solids. It would have taken a chemical analysis to have demonstrated the sophistication. The regulations of the New York Board of Health have demoralized the industry. The present cream standard for milk should be at least 3½ per cent. and after five years it should be made 4 per cent. The fact that the standard is to be raised should be publicly announced so as to encourage the farmer in the selection of the best milch cows. It has been stated that New York obtains its milk supply from a radius of 500 miles. There is no need that milk should be shipped so far. There

are grazing lands in abundance near New York that are available and their use should be encouraged. The shipping of milk for long distance in cans is open to decided objections. The length of time necessary for it to reach its destination adds to the objections to such long shipments. Milk shipped in cans should not be accepted for distribution in New York City if it comes from farther north than Albany or farther west than Binghamton. Where milk is placed in glass and stored in refrigerator cars it does not make any difference how far it may be shipped. Legal regulations would add greatly to the safety of our milk supply.

REVIEWS.

Transactions of the American Orthopedic Association, Thirteenth Session. Held in New York, N. Y., May 31 and June 1 and 2, 1899. Volume XII. Philadelphia: Published by the Association, 1899.

The transactions of this Society appear in a very neat volume of 368 pages, printed upon extremely good paper, and illustrated with about 130 reproductions of photographs or diagrams. There are some fifty-one articles on orthopedic subjects, of which ten are on new instruments. On the whole, this collection of papers shows good work on the part of the members, and the advance not only in orthopedic surgery, but also in the use of mechanical appliances and gymnastics in this specialty.

A Text-Book of Physiological Chemistry. By Olof Hammarsten, Professor of Medical and Physiological Chemistry in the University of Upsala. Authorized Translation from the Author's Enlarged and Revised third German Edition. By John A. Mandel, Professor of Inorganic Chemistry and Physics, and Adjunct Professor of Physiological Chemistry in the University and Bellevue Hospital Medical College. Second edition. First thousand. New York: John Wiley & Sons. London, Chapman & Hall, Limited.

In no department of economics, perhaps, is the law of supply and demand better illustrated than in the province of medical literature. As research advances there is constantly attending it a concomitant widening of the technical horizon and avenues for investigation are perpetually presenting themselves in new directions. But the path of scientific progress is always broadly marked—by a trail of printer's ink, and as each new subdivision of medical knowledge or of allied branches becomes the center of interest there speedily springs up a mushroom crop of special text-books and treatises designed to elucidate it. It is therefore incontrovertible evidence of sterling merit when an older book for years holds its own against the newer comers and maintains its position as a standard in spite of the lucubrations designed to supplant it. Such a one is the volume before us which for over a decade has been the recognized authority in its field and now in its second American edition revised and enlarged from the author's third German issue seems destined to another period of undisputed rule.

With so well known a work, discussion of the subject matter is superfluous, but for those to whom it is new it may be said that it well deserves its reputation of being the most complete and practically useful exposition of the subject in the language.

Proceedings of the Pathological Society of Philadelphia. January, 1900. New Series, Vol. III., No. 3.

F. R. Packard notes that the earliest autopsies recorded in this country were performed about 1674. Jopson and Ghriskey report a case of anthrax with typical vesicular primary lesion but no systematic symptoms until the ninth day, when the temperature suddenly rose and the patient died in an attack of dyspnea. Arthur Meigs states that the small cavities so often seen in microscopical sections of the liver do not, of necessity, indicate fatty degeneration, but may be of a cystic nature. Wadsworth and Spiller report a case of tumor of the occipital lobe, causing atrophy of both optic nerves, a retinitis similar to that associated with albuminuria, spasticity of the legs, and epileptic convulsions. De Schweinitz and Steele report the recurrence of a melanotic sarcoma of the orbit five months after enucleation of the eye, and Eshner describes the symptoms in a case of carcinoma of the esophagus situated three inches from the stomach. J. P. Arnold gives an interesting description of a case of sarcoma in the mediastinum. Summing up he states that the subjective symptoms of such a condition are dry cough, dyspnea, moderate pain, palpitation and general weakness. The objective signs are cyanosis, enlargement of superficial mammary and epigastric veins, edema of face, neck, arm or leg, changes in form and size of thorax, displacement of heart, diaphragm, and liver, abnormal areas of immovable dulness with absence of voice, breathing and vocal fremitus, and a peculiar wheezing inspiration with a sinking of the upper part of the sternum during expiration. In addition are the various signs of pressure upon the mediastinal contents, viz.: aphonia, dysphagia, irregular pupil, unilateral sweating, cardiac irregularities, inequality of the radial pulses, etc. Riesman presented specimens taken from a lioness that had died of suffocation.

A Text-book of Materia Medica, Therapeutics, and Pharmacology. By George Frank Butler, Ph.G., M.D., Professor of Materia Medica and Clinical Medicine in the College of Physicians and Surgeons, Medical Department of the University of Illinois. Third edition. Philadelphia: W. B. Saunders, 1899.

This is the third edition of Dr. Butler's book to appear since the original edition in 1896. We find a number of changes from the original copy, which bears out the author's statement in his preface that the book is thoroughly

revised. Some of the changes are in accord with the criticisms of Dr. Butler's work made in the News when the first edition appeared. The author, however, still refuses to recognize the employment of pilocarpin in eclampsia; he prints the same faulty pictures of dogs poisoned by strychnin; he gives no mention of the untoward effects of cocain when used as an anesthetic; he has amplified, however, several parts of the work which needed it, and has thereby improved it. He tells us now what it is that chloroform can do to the kidneys, but he still persists in attributing great respiratory irritation, even death, to ethyl bromid, without making any modification. When the first edition appeared we feared the book would be dangerous for a student. We confess somewhat to a change of heart; for three editions of such a book cannot appear unless there is something good in it for the student and practitioner. If Dr. Butler will continue to improve each successive edition of his book, as much as he has done this one, we do not doubt that he will eventually succeed in producing one that is above criticism. The publisher has done his full share in making the work attractive.

A Manual of Surgical Treatment. By W. Watson Cheyne, M.B., F.R.C.S., F.R.S., Professor of Surgery in Kings College, London; Surgeon to Kings College Hospital, etc.; and F. A. Burghard, M.D., M.S., F.R.C.S., Teacher of Practical Surgery in Kings College, London; Surgeon to Kings College Hospital, etc. In six volumes. Vol. II. Illustrated. Philadelphia and New York: Lea Brothers & Co., 1900.

The second volume of this work carries out the promise of the first, a practical surgical help to the student, the practitioner and the specialist. As the authors state, only the salient points in pathology and symptomatology are given, treatment, however, being described in detail for each surgical subject considered. As we noted in reviewing the first volume, this is the kind of work which is needed. The ordinary text-book is a compendium of pathology and symptoms; this work is a good supplement to any complete work on surgery.

The present volume treats of deformities, and of the surgical affections of the tissues, the skin, the nails, the lymphatic system, the fasciæ bursæ and muscles, the tendons, the vascular systems and special aneurisms.

As an example of the manner in which a subject is handled, we cite, at random, that of "hammer-toe." A page and a half are devoted to its definition and pathology, followed by three pages of treatment. The treatment advocated for this condition consists of appliances, with illustrative cuts, tenotomy or excision of the head of the first phalanx. These operative measures are succinctly described. The after-treatment is then given in detail.

The entire subject of scoliosis is omitted in this volume, but, it is promised, will subsequently be taken up in the volume on diseases of the spine. We note, too, that Trendelenburg's operation for varicose veins is not mentioned. It is a measure which is in high favor with some surgeons. In justification, however, it must be said that the authors describe, as a rule, only such operative measures as have met with success in their own hands.

As a practical, handsomely illustrated work on surgery, which teaches surgical methods as they are applied in practice, including the preparation and after-treatment of patients, these volumes are undoubtedly destined to meet with unusual success.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

The Principles of Treatment and their Applications in Practical Medicine. By Dr. J. Mitchell Bruce. Adapted to the U. S. Pharmacopœia by Dr. E. Quin Thornton. 8vo., 614 pages. Lea Brothers & Co., Philadelphia and New York. $3.75.

A Manual of Surgery. By Dr. Charles Stonham. In three volumes. Vol. I., General Surgery, 343 pages. Vol. II., Injuries, 383 pages. Vol. III., 725 pages. 8vo. Illustrated. The Macmillan Company, New York and London.

Imperative Surgery. For the General Practitioner, the Specialist and the Recent Graduate. By Dr. Howard Lilienthal. 8vo., 412 pages. Illustrated. The Macmillan Company, New York and London. $4.00.

THE SIGNIFICANCE OF EARACHE IN CHILDREN.[1]

BY T. H. HALSTED, M.D.,
OF SYRACUSE, N. Y.;
PROFESSOR OF LARYNGOLOGY AND OTOLOGY IN THE SYRACUSE UNIVERSITY MEDICAL COLLEGE; LARYNGOLOGIST AND OTOLOGIST TO ST. JOSEPH'S HOSPITAL AND THE WOMEN'S AND CHILDREN'S HOSPITAL.

THE ear, I presume, has been more deliberately neglected by the average physician than any other organ. This unfortunate prejudice against this delicate sense-organ is traditional—it has been handed down from generations of our medical ancestors and was born of ignorance. It is not so very long ago that the medical profession encouraged the laity to believe that nothing smaller than the elbow should ever enter the external auditory canal. It is common experience to-day to meet with patients who come with fear and trembling to consult about their deafness, and who, before submitting to an examination, insist upon an assurance that such examination shall at least do no harm, if it does no good. This fear of being made worse was a fear encouraged by the doctor of but a decade or two ago, who, himself unable to examine and diagnosticate the patient's ear affection, covered up his own lack of knowledge by instilling in the mind of the patient the idea that the ear was an organ which to be touched was but to be injured. Many doctors at this end of the nineteenth century still tell their patients, or, more correctly, the little patients' parents, to pay no attention to the occasional earache, to the evident impairment of hearing, but to leave it to time and to nature and the disease and the deafness will be outgrown. There may have been some excuse for such advice a half, or even a quarter of a century ago, but there is none for it to-day.

Earache is of two very distinct varieties. The one is a neuralgia, when it is best spoken of as otalgia, and in character resembling the pain of a neuralgia in other parts of the body; the other is the pain or ache that accompanies inflammation—a throbbing, beating, steady pain without much intermittence. The neuralgic earache is usually caused by some trouble or disease external to, or quite remote from, the ear itself. The pain may be constant, but usually is sharp and shooting with intermissions of entire cessation. Pressure upon the nerve or disease of the sheath of the inferior dental, for instance, may cause pain in the ear alone. As you enter, with a probe, a cavity in a carious or decayed inferior molar the patient claps his hand to the ear. It is evidently a case of toothache in the ear, comparable with the classical pain in the knee in hip-joint disease. In children old enough to answer intelligently and in adults, if with an acute pain in the ear, there is no deafness, no fulness in the ears, no tinnitus, no redness or bulging of the drum, we have to deal probably with a neuralgic earache, the cause lying either in the teeth, especially of the lower jaw, or some disease of the larynx, such as tubercular or malignant disease, or an acute inflammation of the tonsils, pharynx, or tongue, or malignant and syphilitic disease of these parts. Tumors of the brain or Gasserion ganglion, disease in any part of the fifth nerve, a trigeminal neuralgia, may all occasion otalgia. A beginning furuncle in the external auditory canal, causing much pain but neither deafness nor tinnitus, may be easily overlooked.

The belief that earache in children is ordinarily neuralgic is so prevalent among the laity and, unfortunately, also in the profession, that the statement can be made with positiveness that in children earache is usually a result of acute inflammation of the middle ear and only exceptionally is it neuralgic. I have operated for mastoid abscess upon a number of both children and adults, in whom the earache had been regarded as a neuralgia and treated as such, the patient having been allowed to suffer the tortures of the damned for days, weeks, and in several cases for months, when a correct diagnosis and proper treatment would have obviated not merely all this pain, but, much more important, have prevented a permanent impairment of the hearing or even in one case have saved the patient's life.

The earache of an acute otitis media in a child will vary with the intensity of the inflammation, the age and the temperament of the child, a comparatively slight inflammation and little pressure in the tympanic cavity of one child throwing the patient into paroxysms of screaming or almost into convulsions, while a great amount of pressure with bulging of the drum may in another child occasion only a sense of fulness and discomfort without much pain. The Eustachian tube of an infant or young child is much shorter than that of an older one or of an adult, so that suppuration in the middle ear in young children, because of the easy passage of the discharge, mucus or pus, into the nasopharynx, may be accompanied by comparatively little earache, and without much if any redness or bulging of the drum membrane, the drum being merely opaque or lusterless, and so partly account for the fact that acute otitis media is readily overlooked even by the most careful physicians.

[1] Read before the Medical Society of the State of New York, January 30, 1900.

Infants and small children do not locate the site of the pain in a very clear and satisfactory manner. The child may be simply restless, peevish, toss and roll the head a good deal, at times shrieking with pain either while awake or on waking from sleep. If carefully observed, however, the little sufferer will be seen to bore its head into the pillow on the affected side, try to raise its little fist toward the inflamed side of the head, or an older infant will rub the ear, indicating as best it knows how the seat of the trouble. Unfortunately, the little one's physician or nurse is not always observing and overlooks the fruitless efforts of the baby to make itself understood.

In children at the vault of the nasopharynx, and at, around, or even in the Eustachian orifices is a mass of lymphoid or tonsillar tissue. This tissue is exceedingly prone to acute and chronic inflammation of exactly the same kind as that of the faucial tonsils. A cold in the head in a child is commonly not an inflammation of the nasal mucous membrane but of this pharyngeal tonsil. If a child's throat be examined during an ordinary cold in the head it will usually be found that the nasopharynx is covered with a whitish, croupy exudate, exactly the same kind of an exudate we are familiar with in ordinary acute follicular tonsillitis. In measles, scarlet fever, and influenza colds, this pharyngeal tonsil is always involved. With this swollen mass of adenoids, inflamed and teeming with pathogenic micro-organisms, streptococci, staphylococci, or pneumococci, it is almost inevitable that the child's middle ears should be inflamed to a greater or less degree, and explains at once why children have so many more acute inflammations of the middle ear, so many more earaches than adults.

Remembering that the Eustachian tube, the cavity of the middle ear and mastoid form one continuous bony canal—a bony diverticulum from the nasopharynx—it is readily seen how the inflammation in even an ordinary cold in the head tends to extend to the middle ear; it is also seen how perfectly adapted the middle ear is for the harboring, for the incubating, for the growth and development of bacteria, and because of its magnificent blood and lymphatic supply, an ideal distributing center for bacteria or their toxin products.

The bony plate, the tegmen tympani, which separates the middle ear and cranial cavities, is often, even in adults, not much if at all thicker than tissue paper. In infants and small children it is still thinner, or may be absent, so that an abscess in the middle ear might perforate into the cranial cavity with less difficulty than through the drum. Cerebral irritation is exceedingly common in young children suffering from acute otitis media, and the actual extension of inflammation to the meninges, either through perforation or more commonly along the sheaths of the arteries, veins, or lymphatics, which extend from the middle ear to the brain through the squamopetrosal sulcus, occurs so often that it has long been recognized, that the usual cause of meningitis in children is a suppurative inflammation of the middle ear, just as brain abscess in the adult is often a sequel of acute or chronic suppuration in the mastoid or middle ear. Without doubt some cases of fatal acute meningitis which many of us have seen could have been prevented and the life of the patient saved had the significance of the earache, which was the earliest symptom, been appreciated by the patient, by the parent, or by the doctor, such earache leading to an examination of the drum and to a proper treatment of the acute otitis media before an involvement of the meninges had taken place. The association in children and infants, of acute otitis media with the exanthemata, with cold in the head, and as a cause of acute meningitis has been well known.

Turning to other acute infantile diseases we find that that happens which should be expected from the anatomical peculiarities of the middle ear, especially with reference to its adaptability to the requirements of the favorable growth of bacteria. It is the experience of many physicians to have had a tentative diagnosis of pneumonia, of acute meningitis, even of typhoid fever, upset by the amelioration of all symptoms coincident with a discharge of pus from the ear. As before stated, in infants and small children, perforation of the drum does not occur with the same frequency that it does later in life. The pus finds its way more readily through the Eustachian tube into the nasopharynx, and then to the alimentary tract, or in inspiration the bacteria may be carried into the lower respiratory tract.

During the past two years much has been written, especially in Germany, upon the subject of unrecognized acute otitis media in infants and young children. The subject is one of great importance to the general practitioner because it is he, rather than the otologist, who is in a position to see these cases and it is all important that he recognize the fact that the middle ear is, during infancy, often the subject of purulent inflammation, complicating many other diseases, not simply the exanthemata, but other acute infectious and toxic diseases such as acute gastro-enteritis and bronchopneumonia. Hartman,[1] in 1894, called attention to the connection between acute otitis media and gastro-intestinal affections in infancy, stating that in the latter elevation in temperature and loss of weight should always demand an examination of the middle ears when it would generally be found that the tympanic cavities contained pus, and that with its evacuation through paracentesis of the drum, the temperature would drop, the disturbances in digestion cease, and the body weight increase. He regarded the gastro-enteritis as the result of resorption of the toxic poisons from the exudate in the tympanic cavity, rather than that the otitis media resulted from infection entering through the Eustachian tube during the act of vomiting. In a recent paper Hartman[2] reviews fully the subject of intestinal disturbances caused by otitis media, and reiterates the conclusions of his former paper, published five years ago.

In 1897, Ponfick[3] published the reports of one hundred consecutive autopsies on children under four years of age, dying of various diseases, non-infectious and infectious. The vast majority of them, during life, gave rise to no suspicion on the part of the attending physicians that the middle ears were at all involved, in fact but ten were known to have had middle-ear disease. Of these one hundred, six children died of non-infectious diseases, *viz.*, two of congenital heart disease, one of extensive burns, and three of non-infectious dermatitis. Of these six children, five were found to have had otitis media. The remaining ninety-four were supposed to have died, four of erysipelas and furunculosis, six of diphtheria, one of scarlet fever, eleven of pneumonia, nine of meningitis, thirty-five of gastro-enteritis, sixteen of chronic tuberculosis, three of congenital syphilis, and ten of acute otitis media of which two complicated bronchitis. Of these ninety-four deaths, eighty-six were found on autopsy to have had suppurative or catarrhal inflammation of the middle ears. Of the thirty-five cases of gastro-enteritis, thirty-three had otitis media; of the eleven pneumonias, ten had pus in the middle ear; of the nine cases of meningitis, eight had otitis media; of the remaining thirty-nine cases, thirty-five showed otitis media—most of them with pus in the tympanic cavities.

Had this table of one hundred post-mortems been made up of deaths due to scarlet fever, measles, diphtheria and typhoid fever, the discovery that the middle ear was involved in 91 per cent. would not have been so astounding, but that the table is made up of deaths due to diseases not supposed to be complicated by otitis media is of the utmost significance and immediately the question forces itself, was not, in all probability, the cause of death of a very large number due to the unsuspected, unlooked for, untreated suppuration in the middle ear?

During 1896 and 1897 Barth[4] examined one hundred and twenty-six children under three years of age, suffering from other diseases, and found one hundred and sixteen, or 92 per cent., to have otitis media of greater or less severity—10 per cent. having required a mastoid operation. He states that of six hundred children sick with other affections and examined with reference to their ears, 80 per cent. showed otitis media. Meltzer[5] has investigated fully the relationship that exists between otitis media and bronchopneumonia anl lobar pneumonia in children. He shows very conclusively that if the ears be examined during bronchopneumonia, it will be the exception to find them not involved, and this corresponds with what we should expect. He has, during the past fifteen years, observed a great many cases of lobar pneumonia in children in whom the earliest symptom of the pneumonia is a severe earache on the affected side. This earache occurs at the beginning of the lung inflammation, gradually disappearing during the first three or four days of the pneumonia. He has never seen pus come from the ear during these cases, and thinks the earache due, not to an otitis media, but rather to a sympathetic pain, a neuralgic pain, in a drum already the seat of a chronic inflammation. His explanation of the rarity of suppurative otitis media in lobar pneumonia in contradistinction to bronchial, is, that in the former, hyperleucocytosis acts as a derivative on the otitis media, tending even to arrest and dry up the discharge, mucus or pus, if it previously existed.

E. H. Pomeroy[6] has recently and forcibly emphasized the importance of the general practitioner and especially the pediatrist recognizing the frequency of otitis media in cases of gastro-enteritis and bronchopneumonia, and the necessity of examining the drums in all cases.

At the time of writing this paper there were in the children's wards of the Women's and Children's Hospital in Syracuse twenty-two children under three years of age. Eleven were under six months, the youngest being five days old, and the remaining eleven were between six months and three years. Many were born in the Hospital and remain for care only, being considered in good health. I have examined the drums of all of them finding the examination perfectly feasible excepting in one case, that of a child one month of age, in whom the external auditory canal was so narrow that a satisfactory view of the drums was not obtained. In the cases of a child of five days and of another of two weeks, the view was perfectly satisfactory. In many it was necessary to remove with cotton or a small, dull spoon the epithelial scales which interfered with inspection of the drum. As others have observed, children and infants make almost no objection to the examination of the ears with the speculum, once the auricle is taken hold of preparatory to introducing the speculum. Of the forty-four middle ears which these children presented, twenty were normal, twenty-four showed otitis media to a greater or less degree, five with perforation of the drum with pus, nineteen without perforation or pus in the auditory canal. Of these twenty-four inflamed middle ears, but four were suspected or known to have otitis media—all of these being suppurative. Five of the children had gastro-enteritis, two having pus in the external auditory canal, one a catarrhal otitis media and two normal as to the ears. The one case of acute bronchitis was complicated by purulent otitis media. Three cases of bone tuberculosis showed two normal drums, one perforated drum with discharging pus and three of otitis media without perforation. These examinations are too few in number to have much significance and are offered merely because they tend to confirm other and larger reports.

Recurrent attacks of earache in children mean the presence of adenoids in the nasopharynx. The adenoids may be large, causing nasal obstruction, or they may be very small and not interfere at all with breathing through the nose, but repeated attacks of earache, repeated gatherings in the ear, repeated attacks of deafness accompanying colds in the head mean that there is in the naso-

pharynx, in the neighborhood of the Eustachian orifices, some hypertrophied lymphoid tissue, large or small in amount, which is exceedingly prone to acute and subacute inflammation tending to extend to the middle ear. One attack of otitis media, catarrhal or suppurative, may be entirely recovered from without any loss of function, without any impairment of the hearing, but it is very doubtful whether several such attacks can take place and leave the ear in a normal condition both as to the present and the distant future. Each abscess in the ear means a perforation of the drum membrane, which may heal without leaving a visible scar or it may heal with a very large scar, or on the other hand it may not heal at all, but leave a perforation in the drum, exposing the middle ear with all its possibilities for ill for the remainder of life.

What is the final outcome with reference to the hearing in the case of these repeated earaches which occur during childhood? The great majority of persons, who in early adult or middle life awaken to the fact that their hearing is becoming impaired, are deaf or are surely becoming so because of a chronic catarrhal inflammation or sclerosis of the middle ear. I believe that in a large proportion of these cases the disease began in childhood when the patient suffered from adenoids, accompanied or not by large tonsils. I have traced back from early and middle adult life to childhood, by history obtained from the patient and by the indelible evidences remaining in the nasopharynx, in Rosenmüllers fossa and in the fauces, hundreds of cases bearing upon this statement. Let us assume for the sake of brevity and clearness a hypothetical case and follow the patient from his early childhood to middle life. At from three to five years of age, the patient develops adenoids, has repeated earaches, repeated tubal inflammations until a chronic otitis media, with deafness, increasing during colds, improving after their subsidence, becomes established. The adenoids probably cause nasal obstruction and consequent rarefaction of air in the nasophraynx and tympanic cavity. At about fifteen years of age, or at puberty, the adenoid growth begins to grow smaller through an increase of connective tissue, it becomes firmer and harder but smaller, and consequently lessens the nasal obstruction. At this same period, in the process of development, the nasopharynx becomes much larger, so that the adenoids, as a cause of mouth breathing become both actually and relatively less important. The patient now begins to breathe through the nose, the nasopharynx and tympanic cavities are better ventilated, the drum-head, which has been retracted, begins to assume a more normal position. The patient hears much better, has fewer colds in the head, earaches cease and he believes that he is outgrowing his ear trouble of childhood, as his physician predicted would be the case. This condition of improvement goes on for perhaps ten or fifteen years, when the patient again begins to have colds in the head, the nose becomes obstructed, not this time, however, because of adenoids, but because of a hypertrophic rhinitis. With these repeated colds in the head and with obstructed nasal breathing, the old, dormant, middle-ear disease, which had been quiescent for so many years, is revived and from this time on it proceeds upon its insidious and progressive course, the deafness increasing so imperceptibly that he is unaware of it until a buzzing or some form of tinnitus stirs him to a realization that there is something wrong with his ears and that his hearing is somewhat impaired. He is now thirty, forty or fifty years of age. He consults an otologist, who is compelled to tell him that his disease is essentially an incurable one, and that the most favorable prognosis is an amelioration of the condition, an improvement in the hearing through the benefit that follows the treatment and improvement of his hypertrophic rhinitis and nasal obstruction; but very often, too often, not a single hopeful word can honestly be said, either with reference to improvement in the hearing or arrest of the deafness. It is poor consolation to him to be told that there was a time, in childhood, when the disease could have been cured, or arrested, the hearing restored or deafness prevented, had its presence or its cause been recognized, had the warning of the recurrent attacks of earache and deafness been heeded, appreciated and properly treated.

In conclusion: (1) Earache in children is generally caused by acute inflammation of the middle ear, suppurative or catarrhal. (2) Infants and young children may have suppuration in the middle ear without giving satisfactory evidence of pain, or without rupture of the drum-membrane. (3) In the absence of other known cause of pain, from which a child is evidently suffering, the first cause to be thought of should be acute otitis media, and this calls for an examination of the drum-membrane. (4) It has been shown by examination of the middle ear during life and post-mortem, that purulent otitis media is nearly always present in acute infectious diseases of the gastro-intestinal and respiratory tracts in young children, especially in gastro-enteritis and bronchopneumonia, to which diseases it probably stands in a causative relation. (5) The cause of death in many acute and chronic infectious diseases, in meningitis and in the exanthemata is the result of unrecognized and untreated abscess of the middle ear. (6) Repeated earaches in children are ordinarily but a sign of acute exacerbations of a chronic otitis media resulting from adenoids. (7) In adult life, so-called catarrhal or progressive deafness is often but a final stage of the otitis media which had its beginning in early childhood when it was due to adenoids and practically curable.

CASE OF PULMONARY TUBERCULOSIS SUCCESSFULLY TREATED BY DRAINAGE AND IODOFORM, WITH APPARENT RECOVERY.

By ALEXANDER HUGH FERGUSON, M.D.,
OF CHICAGO, ILL.;
PROFESSOR OF SURGERY IN THE CHICAGO POST-GRADUATE MEDICAL SCHOOL.

S. G., twenty-seven years of age, a colored school-teacher, presented himself at my clinic at the Post-Graduate Hospital March 1, 1899, and stated that for a few weeks he had been losing strength, and that a swelling on his right chest was constantly increasing in size. The swelling, which was situated below the right clavicle, was first noticed two months previously, as a small, hard and painless lump. No attention was paid to it, and it gave but little inconvenience, save only a gradual limitation of a backward movement of the right arm, until now, at the time of examination, this action was entirely prohibited by the enormous size of the swelling. It extended from the clavicle to below the nipple, and from the sternum to the axilla. It was easy to recognize that the pectoralis major muscle was in front of it. *Fluctuation* was very distinct, and not a member of the class hesitated to make the diagnosis of abscess—most probably of a tuberculous nature, even before the examination was completed. A slight cough began six weeks previously, and the patient's strength began to decrease; his weight lessened; his appetite became poor; he was thirsty, and had night-sweats. He had then a temperature of 100° F., a pulse of 100, and respiration was 26 to the minute. The expansion on this side of the chest was less than that on the left side. Vocal fremitus was increased, and a dull percussion note could be detected over the lung, extending from the nipple across the chest towards the spine and about four inches wide. The vesicular murmur was absent over this area. The apex and base of the lung gave signs of functional activity, although not entirely normal. The left lung and the heart were normal. The liver and spleen were slightly enlarged and the feet were swollen. An examination of the blood and urine did not reveal any gross abnormal condition. No tubercle bacilli were found in the sputum.

It was evident that the case was complicated and a serious one. The abscess was assuredly not the most serious condition, but it was that within the chest wall. He had always enjoyed good health previously. His father died of intestinal obstruction; his mother died of consumption. One sister died of "sweating disease," as he termed it, and he has three sisters and a brother living and well.

First Operation.—On March 4th chloroform was given and the abscess sac exposed by a long incision running parallel with the fibers of the great pectoral muscle. The contents of the abscess were curdy, having the appearance of tubercle tissue breaking down. The sac was very carefully dissected out, being ever on the alert for the primary focus. It was found that the third rib near the sternum was diseased apparently with tuberculous osteitis. The carious rib was thoroughly curetted with a bone scoop, the wound closed, drained and dressed. The contents of the abscess were sterile—no germs, living or dead, could be found in it. The microscopical examination of the tissue removed (sac and granulation tissue from the rib), although no germs were found, revealed most clearly tuberculous characteristics. The extirpation of so large a sac is a major operation. The patient stood it fairly well. Hemostasis was complete. During the operation the temperature rose from 100 to 102° F; the pulse count from 98 to 120 per minute, and the respiration from 20 to 24. It was interesting to observe the behavior of the body temperature. The general aspect of the man was that of shock, but the temperature had risen two degrees, whereas to be consistent with shock it should have fallen. The cause of this interesting phenomenon occurring in certain cases during operation is still unknown. It probably indicates some complication.

The next day the patient had a temperature of 103.5° F., pulse 130, respiration 27 and had rested well during the night. He looked so well and felt so easy that I judged him to be suffering from sapremia, and by the third day the pulse and temperature would come down to what they were before the operation. In this I was mistaken; the rapid pulse, high temperature and frequent respiration continued to alarm us for three weeks with but slight remissions. The wound did not suppurate and closed kindly, its secretions remaining sterile. In the meantime the consolidated portion of lung opposite the fifth rib in front became more and more tender to the touch, and the patient could not stand percussion over it. I thought that most likely an abscess had developed in the lung, and decided to deal with it surgically.

Second Operation.—March 25th, with the hope of finding a connection between the third rib, that I had found diseased, and the intrathoracic complication, I began the operation by exposing and removing two inches of it. My efforts in finding the least trace of extension of disease from the rib inwards were futile, whereupon I cut through the pleura behind sufficiently to admit my index finger. Although the apex of the lung had decidedly receded from the pleura, it felt soft, smooth, resilient, crepitant, and it expanded during inspiration. With the full length of my finger in the pleural cavity, and extending it backward over the supposed abscess, what I felt was dictated and taken down by one of my assistants, *viz.*: "I feel a large, hard, unyielding mass, completely filling the chest wall opposite the fourth and fifth ribs. Its surface is rounded, smooth, and delicate adhesions which are exceedingly easily torn and bleed readily are felt, attaching it to the parietal pleura. It is too firm to be an abscess, and too soft for the usual feel of a sarcoma. It seems to me that I could thrust

my finger into its center. Let us explore it still further." After closing the wound in the pleura at this situation, I proceeded to remove two and a half inches of the fifth rib just in front of the mass within the chest. This being done, and cutting through the pleura here, I decided to pack the wound with iodoform gauze, after first suturing the surface of the mass to the parietal pleura, and then wait for a few days before going into it. It was ascertained by one of the interns by listening with a stethoscope that the base of the lung had not ceased performing its function during the operation. Within twenty-four hours the apex resumed its normal work and size.

Third Operation.—Being called from the city, I did not see the patient again for two weeks, during which time he continued to suffer, as before, from high fever, etc. I brought him before the class, and without anesthesia explored the diseased lung. An ordinary grooved director was cautiously pushed through the mass backward to the extent of four inches. Then a Kocher's director was inserted, and afterwards an artery forceps was used, after the method of Hilton, but not a drop of pus was found. With the view of thoroughly clearing up the diagnosis, I removed a substantial piece of the diseased lung and sent it to Professor Klebs' Post-Graduate Laboratory for examination. Being facilitated by the exploratory punctures and the space left by the removal of the tissue, I had no difficulty in introducing one dram of iodoform powder into the very center of what I now felt sure was a mass of tuberculous tissue. All this was done without pain or inconvenience to the patient. Iodoform gauze was firmly packed into the lung as a plug and the wound dressed.

Many as are the strange things that surprise us in our professional experiences, I shall never be loath to mention among them the marvelous change that occurred in this man's condition within the twelve hours after inserting the iodoform into the diseased lung. His temperature came down to 97° F., pulse to 80, respiration to 20, and he expressed himself as feeling better than he had for months. For three or four days thereafter, and also after the majority of treatments, he expectorated blood and particles of iodoform. Once or twice a week, for a period of five months and fourteen days, 1 dram of iodoform, either in the form of a powder or as an emulsion in glycerin, was introduced into the diseased portion of lung, a new part of it being selected each time, until the whole solid area had been perforated and medicated. This was done twenty-eight times in all, the dry powder being inserted twenty-four times and the emulsion only four times. When the emulsion was forced into the lung it caused great pain, furious coughing, and more or less shock; therefore, it was discontinued. The dry powder was inserted through the smallest size of Howard A. Kelly's cystoscopes, the distal end being made pointed. While the instrument was being passed through diseased solid lung tissue no pain whatever was felt, but just as soon as sound tissue was encroached upon, pain and uncontrollable coughing occurred. During the last three treatments no solid tissue could be felt, and they caused great distress, pain, and violent spasmodic coughing. Two of these I performed myself to find out if he could soon leave the hospital. At the end of three months the external wound was closing so rapidly that a short rubber drainage tube was inserted to allow of the treatment being continued. There was a little pyrexia, 99° F., and sometimes 100° F., up to July 8th, but after this the temperature remained normal. Under this date I find the following written on the history sheet: "Has had but a few night-sweats for three weeks, and these were slight; cough absent; appetite good; walks forty blocks a day; fever absent; weight 135 pounds, one pound more than he ever weighed, while on entering the hospital he weighed 119 pounds." It was very pleasing to observe from week to week the most excellent local and constitutional improvements that were being made toward recovery. On the 21st of July, Mr. W. C. Fuchs took two skiagraphs of him, with the instrument inserted into the lung its full length. At this time very little solid tissue was left which could plainly be seen in the radiograph. I am indebted to Drs. Cubbins and McCornack for the attention given to this patient, for notes made of it, and also for faithfully carrying out the treatment outlined. About the middle of April Dr. Jospeh M. Patton kindly examined this case at my clinic, and saw him again a few days ago.

Present Condition.—He performs all his functions as a man as well as he ever did. He has been working since he left the hospital. He weighs 134 pounds which is his normal weight. Since the cold weather has set in, an occasional hacking cough with no expectoration has developed, due, he thinks, to a cold. The condition of the lung as manifested by physical signs is, indeed, most surprising. It is true, he is scarred; the right chest wall is a little receding; slight flatness on gentle percussion is found, but not more than what is common with a thickened pleura. A friction sound, due to adhesion, can be heard, but over the very place where the dulness was greatest and consolidation thickest, a clear resonant percussion note is demonstrable and a beautiful vesicular murmur is present. I can find no evidence of tuberculosis in his lung.

The surgical treatment up to 1897 recommended for tuberculous phthisis is mentioned by Paget in his "Surgery of the Chest," as follows: (1) Injections into the lung tissue. (2) Operation for pyopneumothorax with perforated lung. (3) Operation for the arrest of profuse hemoptysis. (4) Resection of the diseased portion of the lung. (5) Incision of a tubercular cavity. He concludes this chapter by saying: "We have now reviewed the five methods of surgery which have at present been found possible for the treatment of tubercular phthisis; and we have found that two sets of cases where the surgeon may do most

good are those of fetid pyopneumothorax, and those of large tubercular cavity with septic absorption."

In 1898 Dr. J. B. Murphy of this city recommended and carried out *artificial pneumothorax*. In the November number of the *Lancet* of the same year Norman Porritt recommended and also carried out artificial reduction of thoracic space.

Both these methods are advised to be carried out early without waiting for a cavity to form. The one collapses the healthy lung around the tuberculous focus, thus giving it rest, while the other collapses the chest wall on to the lung by removal of sections of ribs in front and behind. The procedure carried out in this case, as far as I can ascertain, has not been hitherto done by any surgeon. The diseased portion of lung is freely exposed by resection of a rib or ribs, as the case may demand, and kept in view while the treatment of direct introduction of iodoform into every corner of the diseased area is carried out as long as it is necessary to effect a cure. Thus attacking the bacillus in its den with a drug that prohibits its growth and stimulates functional activity of the surrounding tissues to throw out a more vigorous granulation tissue to overpower the primary bacilli, this is highly scientific. We are aware that iodoform is the best producer of granulation tissue of which we know, and granulation tissue is Nature's great germicide. Every determination of blood directed to the diseased part by the traumatism produced by the large blunt instrument cannot but have a beneficial effect by virtue of the properties of the blood itself. It must also be remembered that the relief of tension in the solid mass and the drainage of bad blood serum from it have a salutary effect.

Notes of the Case Since December 6, 1899.—The patient was retained in the hospital for observation on account of the pyrexia he manifested the evening of December 6, 1899. In five days, December 11th, his temperature (by mouth) was 96° F., pulse 80, and respiration 19. At 1:30 P.M. of the same day, temperature 100° F., pulse 92, and respiration 20. On this day and at this time (1:30 P.M.) Professor Edwin Klebs injected him in the arm with tuberculosis serum. In three and a half hours thereafter (5 o'clock P.M.) his temperature was 105.4° F., pulse 128, and he coughed so frequently and violently that the respirations could not be counted. This high fever was preceded by coughing, nausea followed by vomiting, and a slight chill. At the end of twenty-four hours the temperature was still 105° F., pulse 138, and respiration 56. During the night he rested fairly well, coughed very frequently and his breathing was labored. Moist crepitant râles could be heard here and there over the right lung. The flatness on percussion increased, urine was scanty (eight ounces in twenty-four hours by catheterization). During the next twenty-four hours his condition was critical; he was delirious, and unconscious most of the time, and had involuntary evacuations of urine and feces; pulse varied from 138 to 160, respiration from 36 to 60, and temperature from 101 to 105° F. From this time he began to improve, so that on the morning of the fourth day his temperature was 99° F., pulse 98, and respiration about 22, but varied and he was able to sit up in bed while an examination of the back was made. There was consolidation of the upper lobe of the right lung, tubal breathing, etc. Over the middle lobe, exactly where the large local tuberculous mass was treated by the iodoform, there was resonance on percussion and a normal vesicular murmur present. This proves the benefit of the treatment that was carried out in this case. The left lung was free from physical signs of an abnormal condition, except along a limited strip in the free border toward the sternum. The sputum contained no tubercle bacilli.

The serum verified the diagnosis of tuberculosis, but the reaction was so furiously dangerous that it nearly killed the patient. Here was a man whose tuberculous right lung was apparently cured by iodoform; no active focus could be demonstrated, but he had developed some fever. On the subcutaneous injection of tubercular serum he was prostrated to death's door.

THE AFTER-TREATMENT OF FRACTURES AND DISLOCATIONS.

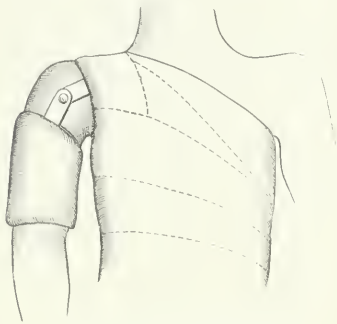
D. N. EISENDRATH, M.D.,
OF CHICAGO, ILL.
PROFESSOR OF SURGERY IN THE POST-GRADUATE MEDICAL SCHOOL OF CHICAGO; INSTRUCTOR OF SURGERY IN THE MEDICAL DEPARTMENT OF ILLINOIS STATE UNIVERSITY.

The frequency with which fractures and dislocations occur both in the practise of the surgeon and the general practitioner and the functionally poor results obtained in many cases seem to justify a closer study of the causes of failure, as well as improved methods of treatment for the purpose of obtaining a more satisfactory result in every respect. Before proceeding further let me briefly summarize our present methods of treating fractures. After an immediate or later reduction of the displacement we apply either a temporary or permanent dressing. The former are represented by side, anterior, or posterior splints of wood, iron, cardboard, fiber, zinc, tin or wire, or the so-called molded splints of plaster-of-Paris, leather, felt, pasteboard, or gutta-percha. These temporary splints may serve as permanent dressings to which may be added silicate of soda, vertical extension, *e.g.*, of the femur in children (Schede) or horizontal extension (Buck's), or the double inclined plane.

In addition to these various forms of temporary or permanent dressings, treatment of fractures by massage has been used to some extent. By some surgeons the ability of massage to overcome swelling, stiffness of contiguous joints, and dryness and coldness of the surface, and atrophy of muscles, has been overrated, and has caused them to demand that we should treat every variety of

fracture by this method. It should, however, be limited to cases where the risk of displacement is slight, as in many fractures at the ankle, wrist and elbow, and of the fibula. It is often impossible to carry this out, as few surgeons can devote half an hour daily to the treatment of a fracture. The ambulatory treatment was strongly advocated by Bruns and others, especially for Pott's fracture and even for those of the femur and patella. The claim which has been made that there is a great saving in time and earning capacity is not borne out by recent statistics, especially

Fig. 1.



Splint applied to shoulder-joint.

those of Krause. There are in addition increased risks of displacement.

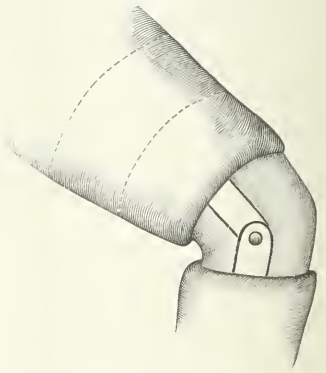
In the treatment of dislocations after the reduction the part is usually kept at rest for a period of two to three weeks, when light, passive motion is begun. Stiffness of the joints, especially those contiguous or distal to the seat of a fracture is a frequent sequel. It is most marked in the old and rheumatic or when sprain accompanies a fracture. The causes are injury of the muscles, edema and infiltration of the capsules and periarticular tissues. Very infrequently there is intra-articular effusion at the time of fracture with subsequent organization of the fibrinous masses and formation of adhesions. Change in the shape of the end of the bone from uncorrected displacement of a fragment or excessive formation of callus may also cause ankylosis. In dislocations we frequently have injury to the soft tissues and muscles around joints, in fact, the same pathological conditions favoring ankylosis as in fractures.

We have all had experiences of which the following is an example. A fracture of the elbow (supracondyloid) in which the arm was kept in a spline or cast for from four to six weeks showed, upon removing the dressing that there was atrophy of the muscles of the arm and forearm and complete limitation of motion, so that a change from the rectangular position in which the arm had been kept was accomplished with the greatest difficulty. For four weeks and sometimes as many months, repeated sittings, at which painful efforts at passive motion are made, had but little effect. The fracture itself will have united, there may be no displacement, but, alas, what is the functional result? This class of cases has interested me so much that I have made a special study of them.

In fractures contiguous to or into joints, we should pay as much attention to the function of the joint as to the fracture. We should not wait until forcible passive motion is necessary, for, as Stimson says, "this is harmful before the second month and even after that time it is far more likely to do harm than good." We create lacerations which require immediate immobilization in order to check inflammatory reaction and which in healing recreate the original or similar conditions. In fractures in which there is a possibility of the adjacent joint becoming ankylosed we should institute passive motion early, say after two weeks, very gently at first, being guided by the amount of inflammatory reaction which follows the manipulation. When the joint is accessible massage is of the greatest value.

Believing personally, however, that active motion by the patient himself is one of the best guides to the amount of exercise which such joints should have, I have applied the well-known mechanical principle of the hinge into casts, and after ten to fourteen days in such fractures, especially those of the elbow, shoulder and foot,

Fig. 2.

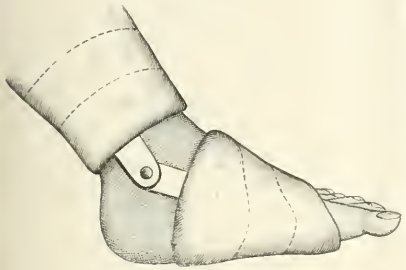


Splint applied to knee-joint.

I have encouraged the patient to make voluntary movements. This mechanism can be easily obtained by having a carriage-smith construct out of a strip of iron three-quarters of an inch wide hinged splints, one each for the outer and inner side of the joint as in the elbow or foot, or an anterior and posterior one, as in the shoulder. These are cheap and can be made for each individual case at a nominal cost. At the end of ten days, in a fracture of the elbow, for instance, the temporary splint is taken off. The arm, with the joint left free, is wrapped up in sheet

wadding, a single layer of plaster-of-Paris is applied, and the splints are held in place while other layers are laid over them. We have thus a jointed cast, and after a few days we may en-

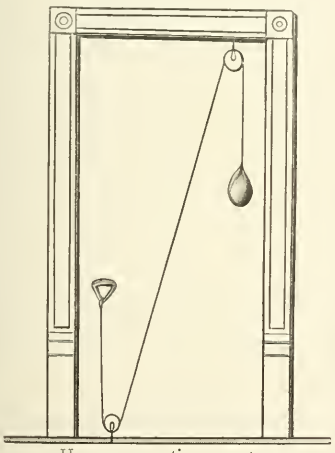
Fig. 3.



Splint applied to ankle.

courage the patient to make active movements, which can be gradually increased, until at the end of the fourth or fifth week it is surprising how great the range of motion has become without any disturbance of callus formation or displacement. In dislocations and fractures, after removing the dressings, massage is an important factor in overcoming the tendency to ankylosis. If the means of the patient permit, I always refer him to a professional masseur who can devote half an hour to an hour to the case daily and in a short time accomplish wonders. Gymnastic apparatus are of the greatest assistance in over-

Fig. 4.



Home gymnastic apparatus.

coming ankylosis of the elbow and shoulder. The best for the purpose is the well-known Whitely exerciser or the inexpensive apparatus shown in Fig. 4, consisting of an ordinary pulley screwed into the door-frame, a piece of clothes-line, with handle, and a sack of salt or sand weighing from three to seven pounds. The sack of salt having been pulled from the floor by the patient, in falling causes the arm to be pulled down in a manner far excelling our manual manipulations. Massage, combined with faradic electricity, and hot packs or the hot air apparatus are of the greatest aid in overcoming the infiltration of the capsule and peri-articular tissues and the muscular atrophy, the so-called atrophy of inactivity, which invariably follows a fracture or dislocation. The massage, etc., may be beyond the reach of our poorer patients, but the apparatus which I have shown can be purchased for such a small sum as to be accessible to all. Our rule should be never to move a joint when it is still very painful and there are signs of reaction, but encourage as soon as possible active motion. If we follow these principles with proper variation for the individual case ankylosis after fractures and dislocations will be far less frequent, and the wage-earning capacity of our patients will be correspondingly increased.

INSTRUMENTS AND APPARATUS USED IN THE DIAGNOSIS AND TREATMENT OF GASTRIC AND INTESTINAL DISEASES.

By H. W. LINCOLN, M.D.,
OF BROOKLYN;
CLINICAL ASSISTANT IN THE DEPARTMENT OF DISEASES OF THE STOMACH IN THE POST-GRADUATE HOSPITAL.

First among the instruments to be discussed is the stomach-tube, of which there are several varieties, each of which has its admirers. There is the one closed at the end provided with two or three large apertures on the sides, the open tube of which the Ewald tube is a good example; and the open tube having rather a sharper edge to its end opening. It is essential, no matter what the physician's choice as to variety, that the instrument be soft and moderately flexible to insure against injury to the gastric mucous membrane. My own preference for general use is for the closed tube of Tiemann & Co. Its average length is about twenty-five inches, with a diameter less than three-eighths of an inch.

The uses of the stomach-tube as a means of diagnosis, are (1) for obtaining test-meals; (2) for determining fulness or emptiness of the stomach in the fasting condition, and (3) for obtaining small pieces of the gastric mucous membrane.

To introduce the tube three points must be observed. (1) When the point of the tube reaches the back of the tongue, command the patient to swallow, and take advantage of that instant to push the instrument on beyond the epiglottis. (2) Have the patient respire forcibly while the tube is in process of introduction, and, in new patients, all the time the tube is in the stomach. (3) Introduce it as rapidly as possible. If the gastric contents do not immediately appear in the

test bottle, blow gently through the tube, which may possibly have sucked in the mucous membrane or be clogged with thick mucus or large food-particles. This failing, move the tube gently back and forth; it may be in too far, or not far enough. If the former be the case the tube curls up on the greater curvature of the stomach, and leaves the openings above the level of its contents. To withdraw the tube, close the external end with the finger, and pull it out quickly but gently. You may recover a sufficient amount of the test-meal in the tube alone for qualitative testings.

Vaseline on the tube or cocaine to the throat are unnecessary in introducing the tube; neither is there any need of using the finger as a guide.

The Stomach Bucket.—Many patients object to the tube, and in many its passage is inadvisable. Here the bucket has its field. The instrument is ovoid, of silver, open at the top; about one inch long by half an inch in diameter. It is attached to a silk thread, which has a knot about sixteen inches from the bucket (the distance from the patient's teeth to the stomach). The thread is looped over the patient's ear to prevent its passage into the stomach with the bucket. Before using, the bucket should be moistened inside and out with warm water, otherwise it will return from the stomach containing nothing but air. To introduce it, have the patient open his mouth wide; use a finger of the left hand as a guide, and with the right place the bucket far back in the throat. Have the patient swallow two or three times, if necessary. Once past the epiglottis, the instrument finds its way easily to stomach. Allow it to remain there for from three to five minutes. Conversation with the patient while the bucket is on its way helps its progress. On withdrawal, the first resistance will be noticed at the cardiac orifice; by gentle traction this may be overcome. Strong resistance is observed at the larynx. At this stage the patient should swallow, when, by a simultaneous pull, the bucket will pass up and out with no difficulty. A pull at this point without the patient swallowing might do damage. Sufficient contents may be obtained for qualitative testing; and quantitative acidity may be approximately determined by the dilution method. The entire procedure is painless and less disagreeable than the passage of the tube.

Esophageal Probe.—Various forms of this instrument have been devised. The best is of whalebone, in two sections or lengths, which screw together. The distal end is threaded, and to it are screwed different-sized hard-rubber ovoids, the principle being identical with bulbous urethral bougies. Its introduction is similar to that of the tube, except that it is not out of place at times to lubricate the bulb. It is of use in determining a narrowing of the caliber of the esophagus and cardiac orifice, and also in determining the presence of growths in these regions.

Gastrodiaphane.—Electric light has been introduced into the stomach for purposes of transillumination by several investigators. The greatest success has, I think, been achieved by Einhorn, whose instrument may be described as follows: It consists of an ordinary soft stomach-tube, to which is attached at the distal end, by means of a silver collar, a small incandescent lamp, connected by wires running through the tube to a battery. To introduce it the tube is moistened as is an ordinary stomach-tube, and passed into the stomach in the same manner. When inside the light may be turned on. A dark room or closet is necessary for this method of examination, and the abdomen of the patient must be exposed. The size and location of the stomach may thus be brought into view, also any growth situated upon the anterior gastric wall will be presented as a dark area in the zone of light.

Intragastric Bag Fitted with Intestinal Intubator.—This apparatus consists of a very thin rubber bag, the exact size and shape of the human stomach. A tube running along the lesser curvatures of the bag acts as a conductor for the intestinal intubator, while a second tube plays the part of an artificial esophagus, entering the bag at the left of the first tube. The instrument is introduced with the bag collapsed and wound around the two tubes. When it reaches the stomach the bag is inflated with air, or may be filled with water. To obtain the intestinal juice, the intubating tube, which is *very thick in proportion to the caliber of its canal*, is passed on through the above-mentioned conductor and enters the duodenum, whence the desired specimen is to be obtained. This apparatus can, with difficulty, be used outside of a hospital.

Gastrograph.—This instrument records gastric peristalsis upon a strip of paper on the principle of a "stockticker." The essential part consists of a hollow, metallic ball about five-eighths of an inch in diameter, made of two hemispheres screwed together. Inside this hollow sphere is a ball connected with the upper hemisphere by a non-conductor, so that it is insulated from it. This ball is covered with small metal spikes, radiating from its center toward the inside of the sphere, *but not touching it.* The apparatus is completed by a minute platinum sphere, which lies between the inner surface of the hollow sphere and the bristled ball. It is unattached and its every motion completes an electric circuit, which records as above stated. The hollow sphere is easily swallowed aided, if need be, by a drink of water. I believe that a stomach found to be empty in the morning, when the patient has had a sufficient meal the previous evening, certifies comparatively normal motility.

Gastroscope.—This is not a new instrument. It operates on the same lines as the cystoscope and has a broad field in the future, although many find objections to its use at present. It is, of course, straight and necessitates dorsal decubitus with the head of the patient dropped. Even then it is not easy to manage, and its use is exceedingly disagreeable to the patient. Naturally all portions of the gastric mucosa cannot be exam-

ined. Its chief indication is in differentiating and determining early growths, provided they lie within its field of detection.

X-Rays.—This method is available for mapping out the size and location of the stomach. The method is to insufflate the stomach with bismuth, which is impermeable to the rays. A metallic capsule swallowed by the patient may be followed on its course, tracing the position of the intestinal tract by means of the X-ray apparatus.

Photography.—Intragastric photography, which was employed as long ago as ten years in Germany, has again come to the fore. The trouble with it is that the minute size of the plate detracts from its possible value.

Having mentioned the best-known instruments for diagnostic purposes, I will now speak of the question of treatment. Here, the tube again holds first place as a lavage apparatus. The simplest form in which it may be used is to attach a glass funnel, holding a pint or quart, to about four feet of three-eighths-inch rubber tubing, and connect this by a glass tube to an ordinary stomach tube, either open or closed. After the stomach-tube is introduced, as for obtaining a test-meal, attach it to the supply tubing. Lower and fill the funnel, raise it and continue pouring in water or the solution until the first *slight* sensation of fulness in the epigastrium is indicated by the patient's countenance; then lower it at once, and allow the stomach to empty itself. Repeat this operation until the return flow is clear.

In my office I use the following apparatus: A graduated supply reservoir holding two gallons is suspended in the same manner as Valentine's irrigator, having the advantage of being able to regulate the pressure of the supply-flow. The supply-tube is attached to the upper arm of the three-eighths-inch glass tube. The stomach-tube is attached to the single arm, and the waste-tube to the lower arm. Hence, by means of stop- or pinch-cocks, one can keep up a nearly continuous current of a desired pressure, and yet have both hands comparatively free, which is of advantage with an inexperienced patient. It is advisable always to have a waste-jar of the same capacity as the supply reservoir. The indications for the use of this apparatus are (1) removal of abnormal amount of mucus; (2) removal of stagnated foods; (3) stimulation of gastric glands; (4) happy laxative effect; (5) introduction of antiseptic and antifermentative solutions.

Intragastric Spray.—This is constructed upon the same plan as the ordinary throat spray. It consists of a stomach-tube fitted at the end with a spray-tip of hard rubber, and having running through it the small tube conducting the medicated fluid. This is attached to an atomizer supplied with two bulbs which give it a continuous spray. The indications for its use are (1) erosions; (2) achylia gastrica; (3) hyperchlorhydria.

Intragastric Electrode.—This is a small ovoid rubber capsule, perforated and containing a copper or brass electrode, to which is attached a wire to connect with the battery. The wire is enveloped in fine rubber tubing. About one-half a pint of water is introduced into the empty stomach, the electrode is then swallowed in the manner as is the bucket, except that the patient may aid its progress by drinking water, the latter being necessary to equally distribute the electricity. The circuit is closed by a flat abdominal electrode, or sponges may be used for this purpose. The galvanic or faradic currents may be used and with good results in (1) erosions; (2) achylia gastrica; (3) gastric atony; (4) hyperchlorhydria.

Gyromele.—This consists of a stomach-tube containing a flexible cable, to the distal end of which is attached a sponge covering a spiral spring. This sponge may be drawn into, or protruded from, the end of the stomach-tube. At the proximal end of the tube and cable is attached a "hand-piece," which makes it possible to very rapidly rotate the sponge in the stomach. The method of introduction is as for other instruments. The flexibility of the cable enables the revolving sponge to reach the different parts of the stomach. The indications for its use are (1) to clean off accumulated mucus; (2) to stimulate the mucosa; (3) to obtain cultures for bacteriological examination.

To F. B. Turck, who introduced the above instrument, belongs the credit for an apparatus constructed with the idea of alternately distending and contracting the walls of the stomach. The operation is termed by him "pneumatic gymnastics." The action is brought about by regulated air pressure. The instrument consists of two parallel attached rubber tubes of unequal caliber; the smaller and shorter one reaches only to the cardiac orifice, the larger and longer to the greater curvature. An air-tank or bulb is attached to one tube, a manometer for regulating the pressure to the other. As a rule the larger tube is used for the "inlet," although in more severe cases the smaller one carries in the air. Air may be drawn through a heated coil, thus using vapor, and here the *entire* mucous membrane derives the benefit of heat and moisture. In subjects with loosely closing gullet or relax pylorus, an intragastric bag is employed, the effect being practically the same as when the air is directly applied, the air acting also as a protector to an over sensitive membrane. Besides the happy effect upon the gastric musculature, both circulation and secretion are markedly benefited.

Powder Blower.—The latest intragastric instrument of which I am informed is the powder blower devised by Einhorn less than twelve months ago. It consists of a piece of rubber tubing not too soft and about twenty-eight inches long. At one end is attached an atomizer-bulb; the other end is fitted with a threaded, hard rubber tip, to which may be screwed the perforated capsules which contain the drug. They are of three sizes according to the amount of medication

desired. A small spoon to fill the capsules accompanies the outfit. The method of use is to fill the capsule, attach it to the tubing and introduce it in the same way as the spray-tube. When it is in the stomach the hand-bulb is forcibly compressed a few times, and on examining with an X-ray apparatus the powder (bismuth) will be found equally diffused over the gastric mucous membrane. If the pharynx contains much mucus, it is well to smear a very little vaseline over the perforations, in order to guard against their being occluded by the above mucus. Good results with this instrument have been obtained in (1) gastric ulcer; (2) hemorrhage; (3) erosions; (4) gastralgia, and (5) in X-ray work as above stated.

Each of the above-described instruments has its field in the diagnosis and treatment of gastric and intestinal diseases. Many, however, of those paying special attention to this branch of medicine, as, for example, Leube, who is one of the most successful gastrologists, depend largely for therapeutic results upon the stomach-tube and lavage apparatus. There is, however, no question, but that the spray, electrode, and powder blower are productive of some of the very best results.

113 Hancock Street, Brooklyn, N. Y.

CLINICAL MEMORANDUM.

TYMPANOMASTOIDITIS.

By EMDON FRITZ, M.D.,
OF MANCHESTER, N. H.

Tympanomastoiditis, as the name implies, is an inflammatory process which involves the tympanic cavity and the mastoid portion of the temporal bone. In comparatively few cases of inflammation in the tympanum is the mastoid invaded, or, if so, the symptoms produced are not of that degree of severity which warrant a diagnosis of mastoiditis. Implication of these bony cells, however, in a suppurative inflammation constitutes so serious a pathological condition that its possibility should always be kept in mind in treating infective diseases of the middle ear. Primary mastoiditis, due to traumatism, syphilis, tuberculosis, etc., will not now be considered. It is not improbable that in some cases where a diagnosis of this affection has been made, there had been at some previous time an inflammation in the tympanum involving the mastoid, and that the morbid process then originated had remained latent, until severe exposure, or some other cause, proved sufficient to awaken active inflammation.

In the class of cases now under consideration there is, primarily, either an acute otitis media, or a chronic suppurative inflammation of the tympanic cavity, which extends to the mastoid antrum and adjacent cells. Remembering the close anatomical relations between these cavities, it is surprising that the antrum ever escapes infection, when there is suppuration in the drum. The peculiar formation of the tympanum, in certain cases, and the arrangement of the mucous folds in the vault of this cavity are probably factors in determining the limits of the inflammatory process.

Acute non-suppurative otitis media is only important in its relation to mastoid complication as being an early stage of suppurative inflammation. Not until the inflammatory process has progressed to pus formation is there liability of serious implication of the mastoid. Acute inflammation in the tympanum, then, should receive prompt and efficient treatment, not merely for the relief of immediate symptoms and the restoration of function, but with a view to preventing a grave pathological condition which not infrequently leads to a fatal termination. Those cases of acute otitis media which develop in the course of some infectious diseases, such as scarlet fever, epidemic influenza, pneumonia, typhoid fever, tuberculosis, and syphilis, are generally purulent from the outset, and are attended with special danger of mastoid complication. Very often in these cases the site of primary infection is in the vault of the tympanic cavity where the reduplications of the mucous membrane and the large proportion of connective tissue are conditions most favorable to suppurative inflammation. The lower part of the tympanum may not be involved in this affection. In the early stage the folds of mucous membrane may be so congested that their increased size shuts off communication between the vault and that part of the tympanic cavity below the short process of the malleus, or, in certain cases, the formation of the parts may be such that inflammatory products find no passage from the vault downward into the lower cavity. The progressive accumulation of fluid in the vault increases the pressure and the gradually yielding membrana flaccida bulges outward into the auditory canal, sometimes completely overhanging the membrane below. If at this stage rupture occurs and free drainage is thus afforded, or if timely surgical interference secures the same result, and careful treatment follows, mastoid or intracranial involvement will probably be averted.

Chronic suppurative inflammation of the middle ear often follows the acute suppurative process. It is occasionally a manifestation of syphilis or tuberculosis. Whatever its origin, a chronic otorrhea should be regarded as a constant menace because of the possibility of infection of the adjacent parts within the cranial cavity, either directly or by way of the mastoid. Septic meningitis, sinus thrombosis, epidural and cerebral abscess, any of these intracranial complications may have their origin in neglected chronic suppurative diseases of the middle ear.

The causes, then, of tympanomastoiditis are primarily those which give rise to acute inflammation in the tympanic cavity, and chief of these is extension of a catarrhal inflammation from the nose and nasopharynx. Forcing fluid into the middle ear through the Eustachian tube in the improper use of the nasal douche, or by the worse

practice of "sniffiing" salt water and other solutions into the nasal passages is a fruitful source of middle ear inflammation. Infectious diseases as causes of acute otitis media have already been referred to. Among predisposing conditions adenoid vegetations occupy a conspicuous place. It has been estimated that more than half the pathological conditions met with in the tympanum have their origin in hypertrophy of the pharyngeal tonsil.

The most notable symptom indicative of mastoid involvement is deep-seated, persistent, dull pain, always worse at night, and, as a rule, limited to the area immediately behind the auricle. Sometimes the tip of the mastoid process will seem to be the most painful point. Very seldom patients conplain of pain in the temporal region. Tenderness on pressure is an important symptom; usually it is greatest directly over the antrum, but the tip of the process will, in exceptional instances, be found to be the most sensitive. Care must be exercised in eliciting this symptom to so direct the pressure that the auricle will not be disturbed, otherwise inflammation in the meatus may be the source of the tenderness which is attributed to the mastoid. If the thumb is placed close to the auricle directly over the antrum and pressure made backward and inward there need be no doubt on this point. Some patients seem abnormally sensitive about the ears, hence it is always well to compare the two sides. The thermometer affords little aid in diagnosis. The temperature seldom runs high, in fact, a normal temperature may coexist with extensive disease in the mastoid, especially in connection with chronic otitis media. Children, of course, show a higher range of temperature than adults. Swelling behind the ear is not a common sign of mastoiditis except in young patients. The cessation of discharge from the ear in connection with the onset of symptoms referable to the mastoid is an important diagnostic sign. The most reliable objective symptom indicative of mastoid involvement is the swelling or bulging inward of the upper and posterior wall of the bony portion of the meatus close to the membrana tympani. Clinical experience proves that before the periosteum at this point is pushed off by pressure from within, the antrum has been invaded. When this symptom and deep-seated tenderness over the mastoid are both found, a diagnosis of mastoiditis is fully warranted. It is not to be understood from this statement that without both these signs inflammation of the mastoid cannot exist, but, finding both, the diagnosis is certain. The following cases illustrate the salient points in diagnosis and treatment:

Case I.—A robust young man, twenty-two years of age, when first seen was suffering intensely with pain in the mastoid region, which had followed what was considered a simple earache, of a few days' duration. There was a scanty mucopurulent discharge. On examination it was found impossible to introduce the smallest speculum because of unusual edema of the auditory canal. There was pronounced tenderness over the mastoid, most marked directly over the antrum. His face bore the expression of extreme suffering. He had not been able to sleep for forty-eight hours, the pain being worse as night approached. It was useless to attempt to incise the drum membrane for it could not be seen. Examination of the other ear demonstrated the fact that he naturally had an unusually small external meatus and moderate edema was sufficient to nearly occlude it. The aural ice-bag was applied over the mastoid and a brisk saline administered. Ten grains of phenacetine were ordered to be given at bed-time, the dose to be repeated during the night if necessary. Diet to be liquid, patient to be kept perfectly quiet. He did not obtain any sleep; during the night the pain was rather less severe; tenderness over the mastoid not appreciably changed; the tumefaction in the canal seemed slightly lessened; discharge about the same as the day before; bowels had moved freely; patient seemed dull and apathetic. The ice-bag was continued and phenacetine ordered as before. Preparations were made to operate next morning if he showed no greater improvement at that time. He slept about two hours during the second night and the pain and tenderness were considerably less in the morning. Ice-bag was continued during the day and he slept several hours. From this time he made an uneventful and rapid recovery.

Case II.—A man forty years of age, of previous good health, had recently suffered a severe attack of influenza. While convalescing he was seized with pain in the right ear. I saw him four days later, when he complained of severe pain, deafness and distressing tinnitus in the affected ear. The drum membrane was much congested, especially above the short process where it projected slightly into the canal. Pain or tenderness referable to the mastoid region was absent. An incision was made through Shrapnell's membrane, from a point behind the short process, upward and through the cellular tissue and fold of mucous membrane of the vault, and the knife was then carried outward through the superior margin of the membrane and along the upper wall of the canal about a quarter of an inch. Frequent irrigation with warm bichloride of mercury solution (1 to 5000) was ordered, and in two days I found him free from pain and with a normal temperature. There was a mucopurulent discharge from the ear and he was instructed to come to my office daily for treatment while continuing the irrigation in the intervals at home. I saw no more of him for four days, when he returned complaining of pain, which I found was due to inefficient cleansing of the canal and consequent lack of drainage. A week later he returned with the statement that for two nights he had been able to sleep but little because of pain behind his ear. The discharge had practically ceased. He complained of nausea and dizziness. There was marked tenderness over the antrum and slight edema of the tissues behind the ear. He attrib-

uted his present condition to the fact that three days previously, being lightly clad, he had driven a team all day in the cold. He was sent to the hospital for the night, and finding his condition worse next morning, notwithstanding the application of the ice-bag and the use of bromides and a saline purge, I decided on an immediate operation for mastoiditis. With antiseptic precautions the usual incision was made immediately behind the auricle, and after elevating the periosteum and retracting the soft parts the cortex of the mastoid was entirely removed with gouge and chisel. Proceeding through the bony structure beneath, as the antrum was approached, there was appreciable congestion and softening, and a small quantity of pus welled up in the blood when the gouge broke into this cavity. All granulation tissue having been curetted away, bichloride of mercury solution was syringed through the antrum into the tympanic cavity, some of it finding an exit through the opening in the drum membrane. The auditory canal and the wound were loosely packed with iodoform gauze and the ordinary aseptic dressing applied. The patient made a most rapid recovery without an untoward symptom.

Case III.—A young woman of twenty-five, never strong, debilitated from overwork, contracted a severe cold followed by a sore throat and in a few days her right ear began to ache. As a child she had been subject to recurring attacks of earache, usually followed by a discharge. For years her hearing had been impaired. I saw her on the second day of the present attack when she complained of pain in the ear and deafness, which was the more annoying because the ear now affected had, until this time, been the better one. Examination revealed moderate congestion of the drum membrane, most marked in the lower half. There was no bulging. She was sent to bed, and a saline cathartic prescribed, after the effect of which one-fourth grain of morphine was to be given. An attempt was made to use the artificial leech in front of the tragus, but as the patient showed signs of swooning only a little blood was drawn. Dry heat was applied by means of the hot water bag. Next day she sent a message that she was better. Instructions were given to keep her quiet and continue liquid nourishment. I did not see her until the following evening when I was told that pain had returned the night before and that she had slept very little. Her temperature was now 101.5° F. The drum membrane was deeply congested and bulging slightly near the posterior periphery. With antiseptic precautions a free incision was made in the most prominent part. Bleeding was encouraged by warm antiseptic irrigation which was repeated at intervals to keep the canal and opening into the drum free. Phenacetine was prescibed in five-grain doses every half hour until three were taken, if necessary, for the relief of pain and restlessness. During the following week her condition was variable. The discharge from the ear, never copious, gradually diminished, but when she became tired, in the after part of each day, the pain would return and she would only sleep under the influence of drugs. Her general condition was bad. Efforts were made to stimulate her appetite and to secure rest by excluding sympathizing friends from her room. She seemed to be gaining some when I was unexpectedly called away and did not see her again for ten days. I then found her suffering continuous pain in and behind the ear. She had not slept, except for brief periods, for several days and nights. The mastoid was very sensitive to pressure over its entire area. Otoscopic examination revealed a swelling or bulging inward of the superoposterior wall of the bony portion of the auditory canal from the membrana flaccida outward. Her temperature was 102° F., pulse 130. She was sent to the hospital immediately and an operation was done the next day. As soon as the cortex of the mastoid was removed, the bone beneath was found to be soft and congested. Having reached the antrum, in using a sharp spoon to remove softened tissue in its vicinity, there was a sudden gush of venous blood which was renewed whenever pressure was removed. The wound was tightly plugged with sterilized gauze, and a firm compress of the same material applied, the operation necessarily ceasing at this point. There was very little subsequent bleeding. The temperature and pulse gradually declined, and she had a good night's rest. The dressing was not removed until the fifth day, after which the wound was cleansed daily and loosely packed. It granulated rather slowly, but the patient made a good recovery and was discharged four weeks after the date of operation.

These cases have been selected because each one fairly represents a certain type. For the purposes of this paper I have thought it better not to report exceptional clinical experiences. More complicated cases, however interesting in themselves, do not as well serve the purpose of illustrating essential points in diagnosis and treatment. In Case I, by prompt measures mastoid inflammation was aborted in the congestive stage. In Case II the site of primary infection was in the attic of the tympanum, and but for severe exposure mastoiditis would have been averted by the means adopted. The subsequent history is typical of extension of acute suppurative inflammation from the drum to the mastoid. Case III began as an acute non-suppurative otitis media. The conditions were such that the disease progressed to the suppurative stage with subsequent implication of the mastoid. The wounding of the lateral sinus during the operation demonstrates the possibility of this accident while keeping rigidly within what are perfectly safe limits in the vast majority of cases. It happens in quite a percentage of operations but does not necessarily interfere with their success, if properly managed.

Application for Otalgia.—Politzer recommends morphine ointment, vesicatories or galvanism, the positive pole to the ear and negative to the neck.

MEDICAL PROGRESS.

Puerperal Infection.—According to A. M. Cartledge (*Obstetrics*, Feb., 1900) the infection atrium of a lacerated cervix is by far the most frequent site of the implantation of septic germs in puerperal infection. The staphylococcus tends to localize with abscess formation, and may be easily overcome by cleansing and drainage; but the streptococcus spreads rapidly by the lymphatics, and soon produces a general septic condition. Fortunately, however, this often spares the tubes and ovaries. In most of the fatal cases death takes place before the formation of abscesses. The indications are early curettage, irrigation, and drainage, and if these measures are not successful, one must, as a last resort, perform vaginal hysterectomy.

Modified Inguinal Colotomy.—R. C. Bailey (*Brit. Med. Jour.*, Feb. 24, 1900) presents a successful modification of the ordinary inguinal colotomy. A two-inch incision is made perpendicular to a line from the umbilicus to the anterior superior spine of ilium at the junction of its outer and middle thirds. The sigmoid loop is then pulled up, its proximal limb sutured all round into the external oblique muscle. A second incision down to the external oblique aponeurosis, parallel to the first and about two inches nearer Poupart's ligament is then made, and the two wounds connected by blunt dissection. The bowel is now pulled down to the second incision and sutured firmly, and the skin wound of the first incision closed. The bowel can be opened according to indications. A light pressure pad may be worn over the subcutaneous portion of bowel to obtain perfect control over it.

Rheumatoid Arthritis.—B. C. Loveland (*N. Y. Med. Jour.*, March 3, 1900) describes the ordinary symptoms and deformities of rheumatoid arthritis, drawing attention to the partial luxation of the phalangeal joints and the characteristic ulnar deflection of the fingers. He sums up the treatment which he has found successful in many cases under dietary, hygienic, including hydrotherapeutic, and medicinal. By dietetic means the patient's blood, urine and digestive ability should be improved as much as possible. Meats should be used once or twice per day. Green vegetables should be used freely. The amount of water to be drunk should not be less than three quarts in twenty-four hours, and tea and coffee should be forbidden. Sweets and acid fruits should be avoided. Under hygienic methods, he suggest moderate exercise, massage, Swedish movements, electricity, packing, sweating, and cool tonic baths. The medicines most useful are the alkalies, most prominent among which are salicylate of sodium and iodide of potassium. The former, when combined with benzoate of sodium, five grains each, given in a glass of water three times a day, may be continued for as long a time as necessary. Where disorganization of the joints has not occurred, a perfect cure, not necessarily a permanent one, will oftentimes result.

Regeneration of Male Urethra.—G. Ingianni (*Deut. Zeit. f. Chir.*, vol. 54, p. 227) has proved by numerous experiments that the male urethra can be reproduced within a reasonable limit. If there is a failure of the normal urethra for a considerable distance, either as the result of injuries, or by reason of operation, for example, amputation for carcinoma, the remaining cavernous and epithelial tissues will grow to make good the defect. A catheter was kept in place to insure the patulence of the new canal, and along it the blood vessels of the cavernous tissue sprouted, while the mucous membrane of the urethra grew outward along the catheter, first in a single layer of epithelial cells, but afterward in many layers. The growth of the cavernous tissue attained its maximum in thirty days, but ceased entirely in sixty days. It was not due to inflammation, but was stopped early if the latter was present. No regeneration of muscular tissue was observed.

Scarlatinous Sore Throat.—Cultures from the throats of over 300 patients with scarlet fever and scarlatinous sore throat have been examined by W. J. Class (*Jour. Am. Med. Assoc.*, Feb. 24, 1900) who reports the results obtained. Of this number 212 were cases of scarlet fever and 88 were cases of angina without any skin lesion, or at least only a perceptible trace. The microorganism previously described by him as the specific scarlet fever germ was found in the primary throat cultures of all 300 cases. In 80 cases the different germs composing the throat cultures were isolated and the "diplococcus scarlatinæ" obtained in pure culture in each. This diplococcus is always present, but in greater numbers when the culture is taken from a scarlet fever throat on the first or second day of the disease. As showing the connection between scarlatinous anginas, or throat lesions identical with those found in typical scarlet fever but without the eruption and scarlet fever, the writer reports three cases in detail in which other evidence, in addition to the presence of the same germ in each, confirms the relationship. In a number of experiments with pure cultures it was found that the blood from a person, who had had scarlet fever, had an inhibitory action on the growth of the diplococcus. Four mice were also used for experimental purposes. Two of the mice received each a subcutaneous injection of five minims of blood, taken from a person who had recently recovered from scarlet fever. All four mice were then inoculated, each with five minims of a solution of a virulent culture of the "diplococcus scarlatinæ." The two mice which had not received the blood inoculation died within eighteen hours, while of the two which had been injected with the blood one lived forty and the other seventy-two hours. The writer's reasons for believing that his "diplococcus scarlatinæ" is the cause of scarlet fever are: (1) The germ is invariably present in the throat secretions, blood

and scales of a patient having scarlatina, and it is a separate and distinct organism not heretofore described; (2) it has been proven to be a pathogenic micro-organism, killing mice, when injected in minute quantities, in from less than one to twenty-four hours according to its virulency; (3) it produces, in swine, a disease the macroscopic lesions of which closely resemble those seen in scarlet fever as it occurs in the human subject; (4) the presence of blood from a patient who has just recovered from an attack of scarlet fever inhibits its growth; (5) the subcutaneous injection of a virulent culture into guinea-pigs will, under certain conditions, produce a nephritis; (6) the experiment quoted in this paper apparently shows that the blood serum of a person who has passed through scarlet fever protects an animal against the invasion of the germ.

Treatment of Typhoid.—During the past few months much has been written about the uselessness of milk diet during the course of typhoid fever, many reports being made of cases receiving solids throughout the disease as routine treatment. C. E. Page (*N. Y. Med. Jour.*, March 3, 1900) argues strongly, however, for an almost complete restriction from even milk diet, believing that the digestive system is unable to assimilate even that amount of food, as a rule, and that by increasing fermentative processes leads to tympanites, diarrhea and autointoxication. He claims that there is no danger of starving a fever patient and that forced feeding is very harmful. He allows large quantities of cool soft water to be drunk, from eighty to one hundred ounces in twenty-four hours, and besides this uses hydrotherapeutic procedures of various kinds. When large quantities of cool water are drunk he finds the invaluable cold bath treatment less often needed and frequently succeeds in allaying disagreeable symptoms and in lowering the temperature by the use of the "damp bandage." This consists of towels wrung dry from cold water, frequently changed and covered by dry towels. Among other valuable means of relieving symptoms he mentions the full cold-water enema as a "nutritive enema," pouring of pitcherfuls of cold water over the patient's head, the narrow cold compresses over the spine, cold compress, massage for the chilly symptoms when the temperature is high, and sponge-bathing. He lays great stress on the value of hydrotherapy in typhoid and believes that when thoroughly and intelligently used the indications for drugs are greatly decreased and the mortality markedly lessened.

Bacteriotherapy of Ulcer of Leg.—In spite of the large number of methods in vogue for the treatment of this affection, Ivan Honl of Prague (*Wiener klin. Rundsch.*, Feb. 4, 1900) describes his own with which he has had a large amount of success. The cases treated numbered 100, all of them carefully picked out of a large mass of cases for their severity. The basis of the treatment is in the application of substances obtained by extraction from the body of the *bacillus pyocyaneus* to the ulcer. The writer does not mean to assume that these ulcers are necessarily due to the germs in all cases, but they are nevertheless responsible for the chronicity and many of the complications of the affection. The cause of the failure of the many kinds of antiseptic applications used may be said to be due to the fact that these germs are not reached by the antiseptics in question, but lie hidden under the scabs and scales of the skin. In all cases which were treated by the extractions derived from the pyocyaneus a remarkable cure was obtained. The method of preparing this pyocyaneus-protein is as follows: The fluid nutrient cultures of the germ have upon their surface a fairly firm skin, a greenish or yellow-green coloration of the fluid also being observed. This culture is prepared by the Buchner method for the extraction of the protein. After successive fractional sterilization, there is obtained a dark-green, slightly alkaline, badly smelling fluid which easily loses its transparency. Its action on the healthy body is practically nil. This fluid is used in the treatment of the chronic ulcers. The patient is to lie down and from time to time bathe the diseased extremity in lukewarm water. The protein is applied twice daily by means of absorbent gauze soaked in the fluid. This is held in place by the proper dressing and the leg allowed to rest. In the 100 cases in which his treatment was used, all were healed definitely and absolutely; no other therapeutic methods were used. There has existed an idea that the protein substances are identical with the toxic bacterial products, but this view, Honl holds, is entirely erroneous. The only effect noticeable after application of large quantities of the protein is a slight swelling at the point of application, due to the presence of large numbers of leucocytes; no constitutional effect whatever follows. The effect of the toxin on the ulcer is evident within twenty-four hours. The secretion of the ulcerating surface markedly diminishes and the new epithelial surface soon makes its appearance. From this stage on the healing process is rapidly consummated and the ulcer is cured.

Santonin in Epilepsy.—After citing the ills of surgical treatment for certain epilepsies, bromide treatment for other epilepsies, with the attendant acne of the skin and degeneration of the mind produced by this method, G. F. Lydston (*Therap. Gazette*, Feb. 15, 1900) offers as a substitute for this class of drugs a remedy quite as efficient as a palliative and perhaps more so as a curative measure. This substitute is santonin. The author disclaims priority in its use, but says that he has used it in the treatment of epilepsy for nearly twenty years, and as yet has never seen it mentioned by any other author. His attention was first directed to the value of santonin in spasmodic affections of children, in whom he has seen it given indiscriminately for spasms whether due to "worms" or not and with whom it was uniformly successful. As a result of his long expe-

rience with the drug he has proven to his own satisfaction (1) upon the average, epileptic patients show better results under santonin than under the bromides; (2) santonin acts well in cases in which the bromides for one reason or another are not at all tolerated; (3) santonin gives distinctly beneficial results where the bromides fail altogether; (4) santonin is free from injurious effects which cannot be said of the bromides. Thus, there is no resulting melancholia, mental hebetude, profound nervous and circulatory depression and disfiguring eruptions. Whatever disagreeable effects santonin may have are not severe, as a rule, and are transitory. If santonin is given, as the text-books on materia medica prescribe, only disappointment can result. Lydston begins in the adult with a dose of from two to five grains. As its taste is not disagreeable he gives it uncombined. The dose is then gradually increased up to the point of tolerance. This he finds to be in many patients as high as twenty grains thrice daily for some weeks. As a rule, the dose is gradually increased to fifteen grains three times a day or possibly four times. The peculiar twitchings about the mouth said to be characteristic of santonin have not occurred in the adult in his experience. The most important clinical feature of the use of the drug is the yellow coloration of the urine accompanied by painful micturition and varying irritability of the kidney. This shows at least that caution in the use of santonin should be used. Idiosyncrasy must be guarded against. In some cases the combined use of bromides and santonin may be desired. A large dose of the bromide is then given at bedtime. The alternate use of santonin and bromides is often of great service.

Schott Treatment of Cardiac Disease.—N. Neesen (*N. Y. Med. Jour.*, March 10, 1900) describes the methods of treatment which are pursued at Nauheim in order that compensation for cardiac lesions may be induced without the aid of drugs. The treatment consists principally of baths and exercises, so regulated that they tend to strengthen the heart's action, having an effect very similar to that of digitalis. The systole becomes stronger and sharper and the diastole longer. In cases of bradycardia, however, the pulse-rate is increased. The baths have all gradations of strength from the weakest (one per cent. of salt) to the strongest (the flowing carbonic-acid baths). The exercises are really resistance movements adapted to the weakest or the strongest patients and given by experienced operators. These are similar in theory and effect to the long used hill-climbing methods for causing hypertrophy of the heart. Professor Schott explains the effect of the baths by supposing that the salt and carbonic acid in the water stimulate the terminal nerve-filaments in the skin, the impulse being carried to the nerve-centers and resulting in an inhibition of the circulatory nerve apparatus. Baths given too long or of too great strength may have a marked weakening effect and should be avoided. It is claimed that all valvular lesions and myocarditis cases may be benefited, but aortic stenosis and insufficiency and initial insufficiency are the ones which are best treated by these methods.

Hemisystole.—Clinical and experimental evidence has led many observers to speak of the occasional absence of synchronism on part of the contractions of one ventricle as compared with the other and the term hemisystole has been applied to this condition. O. Frank and O. Voit (*Deutsch. Arch. f. klin. Med.*, Bd. 65, Hft. 5 and 6) as a result of improved experiments of their own doubt if such a phenomenon ever occurs. Bent catheters were inserted into both ventricles of the hearts of living rabbits and dogs in curare narcosis. Other catheters were introduced into the carotid artery and all instruments connected with manometers which allowed of the registration of the curves. After some of the animals had been partially asphyxiated and others poisoned with helleborein the curves were compared, but no material differences were noticed between the time of the contractions of right and left ventricles. Certain minor aberrations could easily find their explanation in the valvular insufficiency which was present, owing to the abnormal conditions the animals were under.

Lumbar Puncture in Chronic Hydrocephalus.—A. Graber (*Münch. med. Woch.*, Feb. 20, 1900) has seen a cure follow the systematic use of lumbar puncture in one case of chronic hydrocephalus, and a slight, but persistent, improvement in a second. He also noticed that whenever the pressure of the contained fluid was allowed to fall below 100 mm., marked temporal headache and even clonic convulsion were the result. The fluctuations in the level of the fluid during crying or strong expiration could also be well observed. The latter may be ascribed to the stasis of the blood in the veins with expiration and its easier flow back to the heart with inspiration. The fluid was perfectly clear except in a few cases where pure blood was drawn; this, most likely, was due to injury of the subdural and pial veins.

Operation for Fractured Spine.—R. Abbe (*Med. Record*, March 3, 1900) says that operation in cases of fractured spine presents little danger to the patient and causes sufficient improvement to justify the procedure. This improvement may not consist in restored motor power, but in relief from symptoms of persistent meningeal irritation, relief from girdle pains and muscular twitchings, and in an improved vasomotor condition of paralyzed parts. This operation is as logical as that for depressed fracture of the skull. His method of laminectomy which is simple, comparatively bloodless and efficient, is as follows: Cocaine anesthesia preferred; a six-inch incision is made just to one side of the spinous processes and is carried down to the laminæ, between the spinous processes and muscle; the tips of the spinous processes with the interspinous ligament unbroken are separated by cutting pliers; the

muscles on each side are dissected away from the laminæ which, with the bases of the spines, are removed as freely as necessary with rongeur forceps. The immediate signs and symptoms of fracture paraplegia give fairly accurate data for prognosis. If loss of sensation and motion and knee-jerk is instantaneous and complete, the outlook for recovery is almost hopeless. Partial loss of these functions renders a large degree of recovery probable, the cause in such cases being mostly hemorrhagic. Return of motion in cases of complete paraplegia does not always go on to perfect restoration. Wrist-drop or dragging of the foot may persist. In cervical fracture it is usually the fifth vertebral body involved, and this leaves only the diaphragm as a respiratory muscle, innervated by the portion of the phrenic derived from the third and fourth cervical nerves. These cases within a few days develop pulmonary edema and hypostatic pneumonia. Intestinal fermentation with febrile disturbance also frequently occurs in these high fractures. Regeneration of pulpified cord is impossible. Restored function is due to absorption of blood and inflammatory exudate relieving the pressure. Persistent bone-pressure at the site of injury causes increased cord-degeneration and therefore justifies operation. Laminectomy should be done early, and is less painful before meningitis occurs. A radiograph will determine if bony pressure exists.

Resection of Intestine.—The interesting and important question, How much intestine may be resected with safety? has been answered by O. Kukula (*Arch. für klin. Chir.*, vol. 60, p. 887). He has collected the notes of forty published and unpublished cases in which more than a meter of small intestine was resected, or a considerable portion of large intestine, usually a third or more. The amount of small intestine resected varied from 3 feet 3 inches, to twelve feet. The patient who lost the largest amount did not survive, but one who lost 11 feet of small intestine, mostly ileum, did survive and a year later was in perfect health. Chemical tests made to determine his digestive powers showed that they did not in any way fall short of the needs of his body. In thirty-one cases the resection was of small intestine chiefly. Nine of the patients so operated upon died, a mortality of 29 per cent. As no less than seventeen of the resections were done for gangrene, and several of the patients either had peritonitis or were otherwise in bad condition at operation, this mortality is not very high. It was certainly not due to the length of the intestine resected, for of the fourteen patients in whom the resection amounted to more than five feet, only two died, one in collapse and the other of starvation three weeks after the operation. In the case of the latter patient the ends of the intestine were not brought together, as ought always to be done, but a fecal fistula was left.

Six of the nine patients from whom a considerable part of the large intestine was removed died. Four of the six were septic at operation. Analogy, experiments upon animals, and the results of operations on men, have led Kukula to the conclusion that if a patient is in good condition, and the technical difficulties of the operation are not too great, any amount of the large intestine may be removed without risk of permanent damage. He is unable to say just how much of the small intestine may be removed with safety. Animals sustain without future trouble a loss of three-quarters or even more of the small intestine. Certainly in man a half may be removed if necessary. As the length of the small intestine is not known and as it varies much in different individuals, the only safe rule is for the surgeon to estimate the length of the portion which he expects to leave, as well as of that which he expects to remove, before he begins his resection. If he leaves as much as he removes, he need have no fear that the patient will die of starvation. The capacity for assimilation of the portion of small intestine remaining seems to be increased after these large resections, and, further, the large intestine takes on a part of the functions of the small. The well-being of the patient can also be improved by allowing him to take easily digestible food at rather shorter intervals than was the custom before operation.

Acute Pancreatitis.—A case of pancreatic inflammation with unusual symptoms is reported by H. Doerfler (*Münch. med. Woch.*, Feb. 20, 1900). The patient, after an indigestible meal, experienced the most intense lumbar pain which radiated to both thighs and rendered all motion impossible. Several days later fever, rapid pulse, dyspnea and cyanosis developed. The gastric symptoms were only slight, no tenderness was present over the abdomen, but constipation was absolute. It was only when a high percentage of sugar was detected in the urine that the diagnosis could be made. The post-mortem examination showed the pancreas to be the seat of an intense hemorrhagic infiltration. A peculiar condition was seen in the large intestine; the ascending and transverse colon appeared enormously distended, while the descending portion was perfectly empty and flaccid, just as if there had been some obstruction in the gut. This phenomenon the author explains by pressure of the swollen pancreas on certain nerve-plexses which supply the upper colon, thus leading to its paralysis.

Iron in Anemia.—Much has been written of late in regard to the comparative values of organic and inorganic iron, and numerous preparations are being pushed on the market claiming to be of a most absorbable nature and yet entirely uninjurious to the digestive tract. G. M. Linthicum (*N. Y. Med. Jour.*, March 10, 1900) reviews briefly the physiological experiments and the clinical effects which prove indisputably that iron in some form is the essential and the specific in the treatment of anemia, and he believes that inorganic iron is the most efficacious. A desir-

able preparation of iron must meet, however, several requirements. It must be insoluble when administered so as not to injure the teeth; it should not nauseate nor disturb digestion, for the proper food nutrition is the first and most important consideration; it should not be astringent but rather a laxative, and, finally, should be absorbable with the least possible effort on the part of the tissues. These requirements he has found are happily met by a phosphated iron which is insoluble in water as well as in the hydrochloric acid of the stomach. It is suspended in a menstruum, with glycerin preservatives, slightly aromatized and forming a milk-white liquid. The dissolving agent is a tablet containing sodium phosphate, which is taken after the milk-like liquid, causing the formation of a soluble bibasic sodium and iron phosphate which is in its nascent state more readily absorbable.

Bacillus Typhosus Causing Cystitis.—Careful bacteriological examinations combined with the improved methods of differentiating the bacillus typhosus from other similar bacilli have led to the discovery of this germ in many of the organs of a typhoid patient and in the various complicating lesions. The urine has frequently been found to contain these bacilli and a complicating cystitis often has, no doubt, for its germ origin the bacillus of Eberth. A unique case has been reported by T. R. Brown (*Med. Record*, March 10, 1900), in which a cystitis, due to the typhoid bacillus, was no doubt inoculated by catheterization. The case was operated on for a large myomatous uterus and may have received some trauma of the bladder. The urine examination previous to operation showed it to be normal. Catheterization was necessary and the recovery was uneventful until the ninth day, when a severe cystitis developed. Strict aseptic precautions were taken to obtain a specimen of urine, which was found to contain a large number of bacilli which corresponded to all the morphological and biological characteristics of the bacillus typhosus, and gave a typical Widal reaction.

The patient had typhoid fever thirty-five years previously without any subsequent secondary symptoms, and it is very improbable that the germs could have lain dormant in the meantime. Urotropin, five grains three times per day, seemed to have a marked effect in cleaning up this case.

Pneumonia and Tuberculosis.—It is oftentimes found that cases of apparently lobar pneumonia tend to run a protracted course and finally develop unmistakable signs of a tuberculous pneumonia. R. W. Philip (*Practitioner*, Feb., 1900) has published the results of his observations on the relationship of the two conditions after a most valuable experience. He believes that the supervention of a lobar or croupous pneumonia during the course of pulmonary tuberculosis is by no means uncommon. This clinical fact may be observed often enough, but it must be distinguished from a simple exacerbation of a chronic tuberculous inflammation. Further, he has frequently found at autopsy of persons dying of lobar pneumonia the lesions of a tuberculous inflammation in various degrees of activity. Sometimes it would appear clinically that the course of the pneumonia is undisturbed by the tuberculous condition. In other instances it appears to run its course unusually quickly and simply. Walshe says: "Some of the most marked cases of rapid resolution I have met with were in phthisical patients." If the tuberculous pneumonia is far advanced, lobar pneumonia is most serious but it frequently occurs that the tuberculous process is not at all aggravated by the presence of the lobar pneumonia. With reference to the point whether pneumonia may determine the establishment of pulmonary tuberculosis an analysis of a thousand cases showed that in only 0.5 per cent. did there seem traceable a close sequence of the tuberculosis or croupous pneumonia. Other observers give similar figures. Where such a relation appears to exist it must be remembered that the acute condition may have supervened in an already tuberculous lung. In many of the cases of delayed resolution it is probable that the condition which exists is not tuberculous, but an instance of that class of cases in which there is a growth of connective tissue from the first combined with the lobar pneumonia. Examples of this have been described by a number of observers. Again, it must be borne in mind that pulmonary tuberculosis is occasionally ushered in by acute symptoms and signs which may be interpreted as lobal pneumonia.

An Easy Method of Reducing Shoulder and Hip Dislocations.—L. A. Stimson (*Med. Record*, March 3, 1900) for forward dislocations of the shoulder cuts a hole through the canvas about eighteen inches from the head of a cot. The dislocated extremity is passed through this hole, a ten-pound sand-bag is attached to the wrist after the cot is sufficiently elevated, and the patient lies comfortably on the cot until the joint is reduced by the tiring out of the muscles, which occurs usually within six minutes. (This is a modified application of the old method of traction with the arm abducted to a right angle.) In dorsal dislocations of the hip-joint the patient lies prone on a table with the thighs overhanging. The sound limb is supported in extension by an assistant. The other thigh hangs perpendicularly and the foot is raised by the operator until the knee is flexed to a right angle. The thigh is gently swayed from side to side, when reduction often occurs. If necessary, a sand-bag may be placed just behind the knee to assist in the traction on the hip-joint. This method succeeds in four-fifths of the cases.

Phenacetin and Antifebrin on the Blood.—With spectrophotometric methods, A. Denning (*Deutsch. Arch. f. klin. Med.*, Bd. 65, vols. 5 and 6) was able to show that an amount of antifebrin corresponding to 0.685 gm. per kilogram of body weight caused the presence of methhemoglobin in the blood of dogs after thirty minutes to three

hours. The maximum amount was reached after four to six hours. With 60-62 per cent. hemoglobin oxidized, one dog showed complete absence of reflexes, irregular pulse and respiration and a high degree of cyanosis, while with 66 per cent. death usually followed. Phenacetin gave similar results. The temperature was affected differently in different animals, but on the whole there was a general tendency to fall. The respiration, too, varied considerably, but the pulse generally rose and after large doses became small and arhythmic. The lethal dose in case of both drugs was found to be about 5 grs. to the pound of body weight.

Friedreich's Ataxia.—The symptomatology and diagnosis of this disorder are discussed by C. Wickel (*Münch. med. Woch.*, Feb. 20, 1900). Usually seen in early childhood, it may yet appear at puberty or later and rarely after acute diseases. As a rule, it is transmitted from generation to generation, but may be present in only one member of a healthy family. A prominent symptom is the progressive ataxia seen on walking; the patient will control his movements by watching his gait and a slight kyphosis may develop from the constant flexion of the spine. Romberg's symptom is not rare. Choreic movements, increased by motion, loss of muscular power, especially in the legs, nystagmus and slow, irregular speech are further characteristics. Tactile and muscular sense do not suffer except late, when the former may be impaired. Vertigo occasionally occurs as do also lancinating pains, but these only to a moderate degree. No change in the skin reflexes are seen while the tendon reflexes soon are abolished. Loss of pupillary reflex or bladder and rectal control do not belong to this disease. Later, the dorsal flexion of the great toe and the psychical changes give a characteristic picture. Among rare complications are mentioned cyanosis, edema, tachycardia, insipid diabetes and excessive perspiration and salivation. The disease must be distinguished from spinal syphilis, but the latter develops more acutely, shows remissions throughout its course, and leads to paresis or complete paraplegia of the legs; changes in sensation, pains and the symptoms of cerebral lues may frequently complicate the picture. The absence of spastic paresis, increased reflexes and eye and bladder symptoms would speak against multiple sclerosis. There usually is little difficulty in diagnosing from tabes, cerebellar tumor and chronic progressive chorea, while, with reference to *hérédo-ataxie cérébelleuse*, it is to be borne in mind that the absence of patellar reflex, optic atrophy, strabismus, and of diminished pupillary reaction in Friedreich's disease would prevent any error.

Intestinal Neuroses.—W. J. Rothwell (*Medicine*, March, 1900) groups these as disturbances of motility, of sensibility, and of secretion. Of the former we have: (1) Peristaltic restlessness depending upon excessive irritability of the motor nerves of the small intestine, and manifested by rumbling, gurgling, croaking or squeaking. It is especially brought on by emotional excitement, and is not accompanied by alvine discharges as the colon is unaffected. (2) Peristaltic restlessness extending to the colon and upper part of rectum, and followed by precipitate bowel movements. These conditions are benefited by general treatment with arsenic or methylene blue. (3) Enterospasm, due to increased irritability of the splanchnic nerves and indicated by colicky pains and a doughy fecal tumor at or near one of the flexures of the colon. This may be relieved by opium or codeine, warm abdominal cataplasms, and soothing enemata. It is in this condition that the administration of opium may be followed by a movement of the bowels. (4) Ordinary colic, or temporary spasm, due to local irritation. The cutting pains are probably due to the pressure of the contracting muscles on the terminal nerve-filaments, and may be overcome as well by antispasmodics as by anodynes.

Of the disturbances of sensibility: (1) Anesthesia is normal except in the lower portion of the rectum. When this becomes anesthetic, as in hysteria, involuntary fecal passages may result. (2) Hyperesthesia, a feeling of distension without tympanites, or soreness without discoverable organic cause, of throbbings, flutterings, etc. (3) Neuralgia, a boring, pinching, or cutting pain centering about the umbilicus, sometimes accompanied by vomiting and feeble pulse, and suggesting peritonitis, appendicitis, renal or hepatic colic or lumbar neuralgia. However, there is no fever, the constipation is not obstinate, and the pain is relieved by pressure. Of secretory disturbances: Mucous colic, and excessive secretion of mucinoid, nonfibrinous material, coagulating on the inner coat of the bowel and discharged at intervals with colicky pains. It occurs usually in neurotic females and is very resistant to treatment. One may use olive or castor oil as a laxative, cannabis indica for pain, sodium phosphate to prevent fermentation, and salol, resorcin, or bismuth salicylate as disinfectants.

Cough of Influenza.—G. Lemoine, *Bull. gen. de Therapeutique*, recommends the following:

℞ Sodii benzoas.....3i
Bromoform.....♏x
Syrup of tolu.....3i
Syrup of lactucarium.....3iii.
M. Take in twenty-four hours in divided doses.

Syphilis of the Labyrinth.—Begin with the administration of pilocarpin, as follows:

℞ Pilocarpin. hydrochld. .....gr. iii
Aq. dest. .....3ii.
M. Sig. Four drops, increasing to twelve drops a day, to be given hypodermatically.

Unless noticeable improvement takes place within one to two weeks, substitute general iodide or mercurial treatment, also inject a solution of potassium iodide into the ear and prescribe inunctions behind the ear of iodoform, iodol, or mercurial ointment.—*Politzer* (*Landesmann*).

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, MARCH 17, 1900.

BUBONIC PLAGUE ON OUR WESTERN COAST.

We have steadily insisted in our columns that the most imminent danger from the bubonic plague in this country would come on our Western coast. We pointed out also that the danger from the introduction of the disease was much greater at small ports of entry than in the well-guarded harbors of large cities. Our warnings are amply justified by the report of nearly a score of cases of the disease on board a vessel from a Japanese port, now in quarantine at Port Townsend, on Puget Sound. Thanks to the vigilance of quarantine officials, the disease did not according to latest reports succeed in effecting a landing. It has been strictly confined to the ship on which it came from Japan. The quarantine officials at Port Townsend certainly deserve the heartiest commendation from the medical profession and from the country at large for their successful efforts in dealing with this threatened invasion, as well as for the prompt and efficient work by which they accomplished it. Their success should prove a stimulus to the most diligent emulation on the part of the quarantine officials at small ports all along our coast lines.

The danger is steadily on the increase along our Western coast, as our commerce with the East becomes more extensive. With the plague at Honolulu and Manila, in addition to the many points on the Asiatic coast and in Japan, only the most intelligent and painstaking precautions will make us secure. With the warmer weather there comes, as a rule, a lessening of the virulence of the plague in India, but this will not justify any relaxation of quarantine regulations in the midst of our growing Oriental commerce. Prevention must be the watchword all along the line.

The discovery of a case of plague in the heart of Chinatown, San Francisco, lends a new and serious interest to the situation. The unfortunate feature in connection with the case consists in the fact that the investigations thus far conducted have been unable to trace the origin of the infection. To complacently rest on the theory that it is a sporadic case, that it has no antecedents and, probably, no successors, would be criminal negligence. Undoubtedly, the health authorities have a hard fight before them in the face of the popular opposition that has been aroused; but they have the legal authority to apply sanitary precautions to the fullest extent necessary, and will be held responsible by the country if they in any way show the white feather.

ENDEMIC DYSENTERY AND AMŒBIC COLITIS.

Wherever a number of human beings are crowded together under insanitary conditions dysentery almost inevitably develops. Centuries of experience in camps and barracks have demonstrated the fact. The introduction of a specific germ from without is not necessary, for there is present in the intestinal canal of even normally healthy individuals some pathogenic agent that under circumstances favorable to its development takes on a virulence that produces the disease. The conditions that bring about this increase of virulence in one or more of the flora (or fauna?) of the intestines need not necessarily be extremely insanitary. In recent years the hygiene of great assemblages and of army camps has been much more carefully guarded than formerly, yet the attempt to prevent the occurrence of dysentery is still unavailing. Our own recent experience and that of the British in South Africa have been sad proofs of this. The history of our summer militia encampments show

how incessantly natural forces are on the watch to resent breaches of sanitary discipline.

The pathogenic agent at work in these cases remains a mystery. Japan has in recent years suffered from an endemic dysentery that has gradually spread throughout the country. A recent consular report to the United States Government attributes the etiology of the disease to a microorganism that is not unlike the colon bacillus in many of its bacteriological characters. It bears a family resemblance also to the typhoid, and seems in the opinion of competent Japanese investigators to be a member of this colon typhoid group, perhaps a normal dweller in the intestinal canal. Whether this microorganism described in Japan is universal and liable to take on similar virulence under like conditions in any part of the world remains undecided.

A very interesting phase of endemic dysentery in this country was described at the recent discussion on colitis before the Section on Medicine of the New York Academy of Medicine (see p. 432). A number of observers in New York are agreed that there are cases of amœbic dysentery constantly to be found in the city. Careful investigation shows that the disease occurs among people who have never been out of the city, yet whose stools are easily seen to contain active amœbæ in large numbers.

The pathogeneity of the amœbæ that have been found in the stools of patients in temperate climates is by no means generally accepted. Notwithstanding Quincke's work on the subject there are many who doubt if the amœbæ, so often found as an inhabitant of the intestinal tract of people who have never been in the tropics, can ever under any circumstances be the active cause of the dysentery with which it is sometimes found associated. Ordinary drinking water contains active amœbæ in large numbers, especially during the summer. It is from the public water supply almost anywhere in the United States that specimens of this microorganism are obtained for biological study and demonstration. Most of the amœbæ consumed with the drinking water are undoubtedly digested in the stomach, but some of them escape the action of the digestive juices and multiply rapidly in the intestine. Some three years ago at a meeting of the resident and attendant physicians of the Charité Hospital, Berlin, it was accepted that active amœbæ occurred frequently in the stools of healthy individuals who have never had dysentery. Only in the virulent form can the amœba be held responsible.

THE PATHOLOGICAL INSTITUTE OF THE NEW YORK HOSPITALS IN DANGER.

Three years ago the State Lunacy Commission under the leadership of its president, Dr. Carlos F. McDonald, established for psychic research a State laboratory, known as the Pathological Institute. It was the purpose of the Commission to make a new departure; to leave the treadmill-round of clinical observation and citation as carried out in the asylums and strike out new paths in the living phenomena of psychiatry. Those who recognized the dead empiricism of former methods saw in the establishment of the Institute the possible dawning of a new era. These hopes have been steadily confirmed and justified. The correlation of psychologic and medicobiologic sciences in psychiatric investigation was a brilliant conception, and as the Institute has developed and evolved its methods of investigation the conviction has become irresistible that important results are within its grasp. The plan and methods have already thrown altogether new lights on the problem. These are sufficient to justify its existence and demand its continuance. Sufficient time, even in this land of rapid achievement, must be given for such a great work in science to develop on its own particular lines of research before we are justified in demanding of it far-reaching, practical results.

Unfortunately departures from time-honored methods seldom escape opposition. And the Institute is experiencing the usual fate—carping criticism has been present from the first, but this has at length broken out into decisive opposition, and this, too, in the camp of those who were wont to be called its friends. This is the more startling when we consider how inconceivable it is that any one who has the slightest interest in neurology, or psychiatry, or in science in general could be so ill-advised as to pass final judgment on or oppose as well considered a plan of research as is embodied in the Institute. The question then becomes a pertinent one: What are the motives that inspire this opposition. The well-known fact that the practical politicians seldom interfere with established scientific institutions makes the question all the more pertinent. And we, therefore, ask who is responsible for the threatened destruction of the Institute, and what are his motives?

THE SEA-TRANSPORTATION OF WOUNDED.

The success attending the construction and use of hospital ships, as developed in our Span-

ish-American war, has given such an impulse to the science of medical transportation that it seems to have reached almost perfection in the hands of the British in connection with the South African war. The "Princess of Wales," which arrived at Southampton last week with 174 wounded men from Magersfontein and Modder River on board, has achieved the proud record of carrying the entire detachment from Cape Town without a single death. Indeed, many of them when they reached England were on the highway to recovery and the majority of them practically well. As only the seriously wounded men and those likely to be long disabled, or slow in recovering, are sent home by the hospital ships, this is an achievement of which medical science and constructive skill may well be proud.

If the site of the theater of war had been especially chosen with the view of promoting and accelerating the recovery of the sick and wounded in the highest possible degree, it could not have been improved upon. Three-fourths of those who were placed upon the ship at the Cape reached home practically cured. The railroad trip down to the coast, the sea-breezes, and the fresh air of Wynburg are sufficient for the restoration of about half of the sick, and for the remainder the three weeks' sea voyage in a spacious and not overcrowded transport, or luxurious hospital ship, is an ideal climate cure. Beginning in the mild subtropics, the temperature gently warms up as the ship approaches the equator and then cools down slowly again to the tonic snap of the Bay of Biscay, like a well-graduated Turkish bath. Its effectiveness is something wonderful. More than one-half the men landed up to date found themselves fit to turn about and go back at once, and very few of them are unable to walk ashore unassisted, although they had all been carried on board at Cape Town.

ECHOES AND NEWS.

NEW YORK.

Hospital Appointments.—We call attention in our advertising pages to the competitive examination for hospital staff appointments for the German Hospital, to be held April 12, 1900.

Dr. McBurney Resigns.—Dr. Charles McBurney, who for many years has been chief of the staff of surgeons at Roosevelt Hospital, will sever his connection with that institution with the month of March. His resignation was presented to the Board of Trustees of the Hospital February 27th. The cause of the resignation is ascribed to the need of rest. His successor has not yet been appointed.

Mine Disaster Victims.—Three victims of the recent Red Ash Mine disaster in West Virginia, in which forty miners were killed or injured, unexpectedly arrived last week in New York City. The men were all suffering from broken bones and serious contusions and were sent by the police to the Hudson Street Hospital. After their injuries were dressed they were removed to Bellevue.

Medical Legislation.—The bill appropriating $1,000,000 for State care of the insane has passed the Legislature and awaits the Governor's signature. A bill has passed the Senate providing for the abatement of the nuisances connected with the Garbage Disposal Plant on Barren Island, and a bill has been signed by the Governor giving to New York City authority to construct sewage disposal plants. In the Assembly a bill has been introduced which requires the Commissioner of Water Supply of New York City to provide for a proper filtration of the water. Provision is made for the construction of proper machinery, and the Comptroller is authorized to issue special bonds to meet the expense.

Contagious Diseases.—For the week ending March 10, 1900: Measles, 874 cases and 30 deaths; diphtheria, 264 cases and 46 deaths; laryngeal diphtheria (croup), 14 cases and 7 deaths; scarlet fever, 174 cases and 19 deaths; chicken-pox, 25 cases; tuberculosis, 223 cases and 163 deaths; typhoid fever, 13 cases and 6 deaths; cerebrospinal meningitis, 6 deaths. Totals, 1587 cases and 277 deaths.

New Infant Hospital.—Two ladies have given $10,000 to the Children's Aid Society of Brooklyn for the building of an infants' hospital and a beach pavilion, as an extension to its other buildings used in the summer at Coney Island. This hospital will be reserved for cases of critical illness. The buildings will be completed in time for the summer season.

Pemphigus at Bellevue.—More than thirty physicians were at the Bellevue morgue on the evening of March 9th to witness an autopsy made by Dr. Ewald upon the body of a man, twenty-four years of age, who died from pemphigus, an exceedingly rare disease in the United States. Pain in the face was first complained of; this was diagnosticated as neuralgia. He had polyphagia to a marked degree eating more than ten grown persons would usually eat. The most characteristic skin lesions were vesicles containing serum.

A Step too Far.—About twenty boys and girls in the new High School in Williamsburg witnessed, on March 7th, the chloroforming to death and dissection of a cat in order that a practical demonstration of the anatomy of the animal could

be given by Professor J. K. Van Demberg. The bad impression which must have been made upon these young people is very likely to have far outweighed whatever good may have resulted from the demonstration.

Geneva's Smallpox Expense Claim.—A claim of $2386 arising from the importation of smallpox into New York State in 1898, by the Joshua Simpkins Opera Company, was filed in Albany on March 10th by the City of Geneva. A mild epidemic or smallpox in that section originated with a member of the company. The company went to Geneva, where its twenty-six members were placed on the steamer "Onondaga" and quarantined on Seneca Lake for several weeks. The city's claim is for the cost of the quarantine.

The Medical League.—The Secretary of the Committee on Charities and Legislature of the New York Medical League submitted its annual report at the meeting held January 15, 1900. The report narrates the active part taken by the Committee in securing the passage of the present Dispensary Law, and also its success in checking the growth of unnecessary charities in preventing the Home for Incurable Cancer securing a charter. The report commends Comptroller Coler in the attitude he has assumed toward public hospitals and dispensaries. The Committee also took an active part in resisting the incorporation of Emanuel Hospital. The suppression of this institution was one of the first fruits of the new Dispensary Law. The Committee also closes its report by urging upon the entire profession more attention to public duties as a part from the mere grinding out of fees, and the desultory work done in hospitals and public institutions. The Committee regrets "that the profession is not sufficiently interested in these matters to take the time and trouble to work at problems which concern us all, not merely as medical men, but as residents of the largest city in the Union."

Obituary.—Dr. Charles E. West, a pioneer in the education of women and for many years the head of the Brooklyn Heights Seminary, died on March 9th. He was born in Washington, Mass., in 1809, and was graduated from Union College with the class of 1832. In 1839 he became principal of Rutgers Female Institute, and during his twelve years' service in that capacity he outlined a plan of college-work for women which was the precursor of the course at Wellesley and Vassar. He received the degree of A.M. from Union and Columbia, that of M.D. from New York University, and that of LL.D. from Rutgers. A son and two daughters, one of whom married Dr. William P. Northrup of this city, survive him.

PHILADELPHIA.

Influenza.—The Board of Health reports an epidemic of influenza. Several hundred cases have developed and five deaths from this cause occurred last week.

Resignation.—Dr. John Ashhurst, Jr., Professor of Surgery in the University of Pennsylvania, has resigned that position, the resignation to take effect at the close of the present session.

Osteopathy.—The Pennsylvania Association of Osteopathists was organized at a meeting held here last week, Dr. O. J. Snyder of this city being chosen president. Efforts will be made to have the practice of osteopathy legalized in this State.

Health Report.—Deaths in the city for the week ending March 10th were 511, a decrease of 85 from the previous week and a decrease of 9 from the corresponding week of last year. Contagious diseases: Diphtheria, 82 cases, 20 deaths; scarlet fever, 54 cases, 3 deaths; typhoid fever, 84 cases, 10 deaths.

Contagion Feared.—Citizens residing near Thirteenth Street and Lehigh Avenue are alarmed by a report that the trustees of the Rush Hospital for Consumptives are negotiating for a building at that place. A petition averring that said hospital would be prejudicial to the health of the locality has been presented to the owners of the property. It is interesting to note the names of two physicians among the signers.

Celluloid Thread.—At a meeting of the College of Physicians, March 7th, Dr. W. W. Keen presented a report upon the use of celluloid thread in surgery. He and other members of the surgical staff of the Jefferson Hospital have used it with satisfaction. Experiments show that the tensile strength is increased by sterilization, dry heat more than doubling it. The thread absorbs fluids to 41 per cent., this being the most marked disadvantage thus far discovered. Experiments regarding its absorbability are in progress.

Pathological Society.—At the meeting of March 8th Dr. A. O. J. Kelly spoke on "Tumors of the Vermiform Appendix." Of 760 appendices removed at the German Hospital four contained malignant growths, three of these being only microscopic in size. Three of the growths were primary. The clinical symptoms were those of appendicitis. Dr. Frazier reported a case of oxyuris vermicularis in the appendix. In another case a segment of tapeworm was found in the appendix.

Women Army Nurses.—A meeting of physicians and nurses was held March 10th to discuss the bill providing for the employment of women nurses in army hospitals. Dr. S. Weir Mitchell said that the Surgeon General should be placed at the head of the corps of women even if he had under him a woman superintendent. No nurses should be appointed to the army except by competitive examination. This point he considered very important and urged that a clause, stipulating it, should be incorporated in the bill. Mrs. J. R. Hawley spoke of the progress of the bill and of the objections being raised against it. Dr. W. W. Keen is heartily in favor of the bill, but would have some changes made. The number of nurses should be increased and the service made

to include transports, hospital ships, and field-hospitals. No woman nurse should be sent to the front. He is not sure of the expediency of a woman superintendent of hospitals, but if this should be decided upon the superintendent should be one who has risen from the lowest ranks by promotion.

CHICAGO.

Superintendent of Alma Sanitarium.—Dr. George F. Butler of this city has been appointed Superintendent of this Sanitarium at Alma, Michigan, to succeed Dr. E. S. Pettyjohn, the appointment to take effect May 1st. Dr. Butler will retain his college connection with the Chicago College of Physicians and Surgeons, and will continue to edit the *Doctors' Magazine*.

Examination of Osteopaths.—On March 6th a class of 21 osteopaths from Illinois and surrounding States took a special examination before the State Board of Health for licenses to practice osteopathy in Illinois. The branches in which they are required to pass a successful examination are anatomy, physiology, chemistry, histology, pathology and hygiene. The license does not permit the administration of medicines or the use of instruments in performing surgical operations.

Vital Statistics.—During the week ended March 3d there were 537 deaths recorded by the Health Department. For the first two months of the current year there were 4396 deaths in Chicago as against 4736 for the corresponding period of 1899, a decrease of 342 for the current year. This diminished mortality is due to fewer deaths from pneumonia, influenza, typhoid fever and nervous diseases. The medical inspectors of schools examined 4079 pupils, and of that number excluded 348 because of the danger of infecting others. One hundred and thirty-six bacteriologic examinations were made in the city laboratory; 67 cultures from children's throats were made for physicians for the purpose of determining if children had diphtheria, and the bacillus of the disease was found in 11 of this number.

Visiting Nurse Association.—This Association has been of the greatest value to the city Health Department in its work. This is particularly noticeable in its efforts to suppress contagious disease. Nurses have been most diligent in ferreting out concealed cases and reporting them, and the individual effort that is made by the nurses in teaching those who so much need it the value of isolation in contagion, the value of antitoxin in the cure of diphtheria and vaccination in smallpox, together with the value of the generous use of soap and water and general cleanliness of person and habit, is a gentle and valuable influence that cannot be coldly calculated in dollars and cents.

Eye and Ear Symptoms in Brain Tumor.—Dr. William H. Wilder discussed this subject at a joint meeting of the Chicago Medical and Neurological Society. In the list of general symptoms he put optic neuritis second to headache. Optic neuritis should be looked for at once in all cases of suspected focal disease of the brain, for it may be present although normal central vision exists. The writer found mention of this sign in a hundred and four cases out of a hundred and forty cases of brain tumor recorded in the literature for four consecutive years. Another important general eye symptom of brain tumor, although less frequent than the former, is temporary periodic blindness, coming on in the early stages of the growth. Hemianopsia may be an important localizing eye symptom of brain tumor. The ear symptoms relate principally to the labyrinth and the auditory nerve, and consist of subjective sounds and varying degrees of deafness. Careful exclusion of middle-ear disease is necessary before formulating any conclusion as to the relation of ear symptoms to a possible intracranial growth.

Dr. Weller Van Hook discussed recent work in the surgery of brain tumors.

Socio-Legal Forum Meeting.—This Association, which is composed of physicians, lawyers and sociologists, recently held a meeting at which was discussed "Heredity as a Factor in Developing and Maintaining Crime and Criminals," the essayist being Dr. Albert Schneider. Among other things he said that one boy will steal and lie for the same reason that another is honest. It is natural in either case. Acquired characteristics may be transmissible to the next generation to the same extent that inherited characteristics are. Criminals, like poets, are born, not made. Crime is born of crime. The alcoholic habit is not inherited, but the tendency to become a victim of the habit is inherited. One of the most important matters that should be considered to-day is the prevention of marriages among paupers, criminals, dependents, and delinquents of all kinds. In the discussion Dr. Daniel R. Brower said that the criminal is usually the subject of the tyranny of his construction. The basis of his character is found in the preceding generations. The law with its conservatism has failed to recognize this fact. The crime and not the criminal has been the consideration. The laws should be changed so that the criminal is the consideration. Dr. W. Xavier Sudduth advanced the theory that environment and tradition are stronger influences than hereditary characteristics, and this difference was discussed pro and con by nearly all the members present. Tradition and environment have more to do with the place of man in the social scale than heredity. Every child is by nature a savage, and it is his early training that has a large influence in making him one thing or another. A tendency may be inherited, but a habit seldom is.

Kidney Affections in Pregnancy.—Dr. J. Clarence Webster read a paper on this subject before the Chicago Medical Society. In 1848 Virchow pointed out that, of all the organs in the female organism, the most frequent functional or structural alterations due to pregnancy are found in

the kidney. Sugar is found in a considerable number of cases of pregnancy, and more frequently after delivery, but this is only milk sugar absorbed from the breasts, not true glucose. The latter is no more frequent in pregnancy than in the non-pregnant state.

With reference to the occurrence of albumin in the urine and its significance, there is great difference of opinion. Its frequency has been variously estimated by different workers. According to recent observations, serum-albuminuria occurs in about 2 per cent. of all pregnant women who are healthy at the beginning of pregnancy. The process of labor causes albuminuria in a still larger percentage of cases. The investigations of the late Sir Thomas Grainger Stewart appear to justify the view that there may be an albuminuria, which is to be regarded as a psysiologic peculiarity and not the indication of a pathologic process. A priori, then, it must be conceded that a like explanation may suffice for some cases of the albuminuria of pregnancy. In a small number of cases the kidneys may not recover from this condition after labor, but may pass into a permanent true parenchymatous nephritis. In the majority of instances, however, there is every reason to believe that they may be restored to their normal condition in a short time.

With reference to compression of the ureters, Halbertsma of Utrecht, from his studies of eclampsia, believes that increased intra-abdominal pressure due to the pregnant uterus, may, by interference with the functions of the ureters, lead to alterations in the renal structure. He thinks that the special tendency to these alterations in primiparæ, hydramnios, multiple gestation, contracted pelvis (in all of which the pressure is increased), strengthens his view. Ries believes that in some cases compression of the ureters by the presenting part of the fetus is the most important factor. The essayist believes that too little attention has been given to the opinions of Halbertsma and Ries.

The treatment of a pregnant woman with symptoms pointing to disturbed renal functions is to be carried out on the lines followed in the non-pregnant state. The strictest watchfulness on the part of the physician is necessary.

GENERAL.

Grip in Boston.—Grip has assumed epidemic proportions in and about Boston. The Board of Health reported 19 deaths from it for the week ending March 10th.

Professor Osler.—It is stated that Dr. Osler, Professor of Medicine at Johns Hopkins University, is to be asked to allow himself to be nominated to the Chair of the Practice of Physic in the University of Edinburgh. The *Medical Press* in this connection avers that the Doctor's reputation is as great in the Old World as in the New.

Mutter Lectureship.—The next course of ten lectures instituted by the late Professor Thomas Dent Mutter, M.D., LL.D., on some "Point or Points in Surgical Pathology," will be delivered during the winter of 1902-1903 before the College of Physicians of Philadelphia. The compensation is $600. The appointment is open to the profession at large. Applications, stating in full subjects of proposed lectures, must be made before October 1st, 1900, to the Committee on the Mütter Museum, and should be addressed to John H. Brinton, M.D., Chairman, Northeast Corner of Thirteenth and Locust Streets, Philadelphia, Pa.

Gynecology, Surgery or Medicine?—It appears that in England gynecology is definitely set down as a branch of surgery, instead of a department of medicine. In a recent announcement of a vacancy for a surgeon for diseases of women, it was stated that candidates must be Fellows of the Royal College of England; in other words, no member or Fellow of the Royal College of Physicians need apply.

Science Classified.—Sir Michael Foster who is one of the Parliamentary M.D.'s, in a recent speech classified the various aspects of science into: The science *militant*, tilting against every known tradition, the extreme wing of which he denominated as the science *blatant*, always making pretensions for science to which science itself makes no claim. The science blatant is preached by men who have taken no part in the fight, but have stolen the trumpet from some one and simply blown it. Then there is the science *vigilant* which is always seeking occasions for advance; and the science *mendicant*, which, like the daughter of the horse-leech, is always crying, "Give, give!"

Decorated Sausages.—Before the English Government Commission upon Food Preservatives Mr. Walter Fisher, President of the Society of Public Analysts, recently testified that the practice of using coloring matter in food was alarmingly upon the increase. He declared that he had even known of coloring matters which were themselves artificially colored. To this Professor Thorpe added in corroboration that sausages might be found whose exterior was covered with an aniline dye, and whose interior was tinted with a preservative containing Bismarck brown. Mr. Fisher replied that he had heard of such double-dyed deception, but had never examined sausages professionally, nor had he supposed them capable of such rich adornment. Sausage has always been a synonym for mystery, but that its nefarious dark compounds were also frescoed and hand-painted in elaborate style is a fresh revelation of its duplicity.

Mania a Sero.—The *Practitioner* cleverly announces that a severe epidemic of a new form of insanity appears to be setting in. With *mania a potu* we are sufficiently familiar; now we begin to make acquaintance with *mania a sero*. This remarkable affection does not attack patients but the physicians, and the symptoms are particularly severe in those who themselves make the

serum. Already we have a serum for nearly every known disease. Metchnikoff is about to abolish old age. This, however, depends upon the supply of guinea-pigs. Old age being disposed of, the next thing is to attack vice. A horse subjected to drugging with whisky is supposed to yield a serum which will reform the most inveterate drunkard. As some of the vices cannot well be inoculated into animals, however, we shall eventually reach a condition in which human subjects will have to be employed. "It will doubtless be a comfort to old sinners," says the *Practitioner*, "to be of some use to their kind before they depart this life by furnishing serum that will serve to produce immunity from their vices in others."

Candy for the Soldiers.—Fifty tons of candy have been sent to the soldiers in the Philippine Islands by the Commissary Department of the army during the last three months, and large amounts to the soldiers in Cuba and Puerto Rico. This is done upon the advice of the medical as well as line officers of the army, because it is a physiological fact that in the tropics a moderate consumption of confectionery promotes health and satisfies a natural and not unhealthful craving of the stomach. Candy was never furnished to the United States army before, although it is commonly used as a ration by the British and French troops in the tropics. The larger part of the shipment are chocolate creams and lemon and other acidulated drops, which are hermetically sealed in one-pound tins of oval shape to fit the pocket of a soldier's uniform. The candy is manufactured in New York especially for the Commissary Department and is little more than sugar and lemon or lime juice. It is probable that sugar henceforth will form a part of the soldier's regular ration.

The Russian Method.—The Russian Government has grappled with the question of the overproduction of medical practitioners in a drastic manner peculiarly its own, states the *British Medical Journal*. The admission of first-year students by the several medical faculties throughout the empire is restricted to a fixed number. The total number of first-year medical students in the dominions of the Czar is thus fixed at 1095. This number does not include the students of the St. Petersburg Medico-Military Academy, which is allowed to admit 250 first-year students.

Smallpox in Morristown.—While walking through the public square in Morristown, New Jersey, on March 10th, Dr. James Douglas noticed that the face of Isaac Quimby, one of a group of boys who were playing, was covered with an eruption. He made a diagnosis of smallpox and conducted the boy to the pesthouse, walking on the sidewalk while the boy walked in the road. Two weeks ago a member of the Quimby family was taken ill with the disease, yet since that time this latest victim has been on the streets daily. The local Board of Health is greatly censured for permitting young Quimby to be at large, and possible developments are anxiously being awaited. Three new suspicious cases were reported to the Board of Health on March 10th, and a strict quarantine was established around the houses of the patients.

Dr. Barker and Dr. Bardeen.—Dr. Llewellyn F. Barker, Associate Professor of Pathology of the Johns Hopkins University Medical Department, has accepted the Chair of Anatomy and Neurology at the University of Chicago. He will teach also in the Rush Medical College. He will assume his new duties at the beginning of the next term of the University.—Dr. Charles Russell Bardeen, who is Associate in Anatomy, will become Professor of Anatomy in the University of California.

Health of Troops at Manila.—Surgeon General Sternberg made public, on March 12th, a statement showing the number of sick soldiers in the Manila hospitals, as given in the weekly cable reports since January 20th. The report is as follows: January 20th, 2540; January 27th, 2389; February 3d, 2051; February 10th, 1630; February 17th, 1613; February 24th, 1531; March 3d, 1434; March 12th, 1287. It appears by these data that since January 20th there has been a decrease of nearly 50 per cent., mainly due to the complete recovery of many of those who were ill. It is reported that the Manila hospitals are in excellent condition and that the bubonic plague has been fully checked, if not conquered. Major Brown, who has charge of the Sanitary Inspection Department, has been able to reduce his corps of inspectors nearly one-half.

The Plague.—The number of cases of the plague at Calcutta is steadily on the increase. There were 411 deaths from the disease there during the first week of March. This is causing a great exodus of merchants from the city. At Sidney, Australia, three new cases of plague were officially reported March 11th. At Buenos Ayres a number of cases of plague have been officially reported. Vigorous quarantine measures are being enforced. At the Cabinet meeting in Washington the recommendation of the Hawaiian Council that they be authorized to spend $300,000 in the suppression of the bubonic plague, and in the relief of distressed natives, was formally approved. The opinion was unanimous that the gravity of the situation justified this expenditure and the necessary directions were forwarded at once.

At San Francisco the Board of Health began, March 12th, a house-to-house inspection of Chinatown, because its members are now firmly convinced that the Chinaman who died a week ago succumbed to genuine bubonic plague. This decision was reached after hearing the testimony of the Federal quarantine officer, Dr. Kinyoun, who reported that all the animals which had been inoculated with virus from the body of the Chinaman had died, and autopsy demonstrated the presence of bubonic plague. His diagnosis was concurred in by several other bacteriological ex-

perts. As this case may have been merely sporadic, the board decided not to quarantine Chinatown, but to establish a systematic inspection of the quarter and to insist that all sick Chinese shall be brought for treatment to white doctors. It was also decided to clean Chinatown.

Physique of the Boers.—The London *Lancet*, commenting on the physical condition of the Boers due to their pastoral life and outdoor occupations, says: In so far as they are of Dutch descent, the Boers should be small. The French blood which is mingled with that of the Dutch would not tend very considerably to increase the height of the Boer. The French, although taller than the Dutch, are not so tall as the English. Yet the Boers of to-day are taller, stronger, and possess a more powerful physique than the English. It is quite a common occurrence to meet a Boer six feet six inches in height. Indeed, it has been said that the average height of the Boer is six feet two inches. All travelers bear witness to their magnificent physique, especially those who have been among the real Boers, that is to say, those who live in the rural districts well away from the railway lines.

But apart from the flesh and bone, the big, strong frames, and the hard muscles developed by the healthy, constant out-door exercise, the Boers have practical freedom from the diseases due to alcoholism and vice. They are not total abstainers, but they are remarkably sober, and drunkenness is rare among them. On the other hand, how often are British soldiers punished for drunkenness and invalided through venereal disease. Not only is almost every Boer physically fit to take the field and fight for his country, but he is a stronger, healthier, and bigger man than even those who have been selected by medical examination as fit to serve in the British army.

From this the *Lancet* deduces the lesson that the physical salvation of the human race is to be obtained only by securing at least a reasonable proportion of the fresh air, sunshine and out-of-door life that is enjoyed by the Boer.

Medical War News.—There are now no fewer than seven consulting-surgeons with the British forces in South Africa, each receiving pay at the rate of $25,000 a year, or a total of $175,000. The *Practitioner* remarks that, of some of them, it may be said without the least reflection upon their professional position that they had blushed unseen within the walls of their hospitals before this greatness was thrust upon them. The men, of course, are worth it and more than worth it, but the question is asked: Is the work which, in the peculiar circumstances of the case they are able to do, worth it?

The siege of Mafeking continues and all the horrors and suffering of Ladysmith are being experienced here. Two hundred and ninety-two persons have been killed, wounded, or have died of disease since the siege began. Typhoid malaria and dysentery are epidemic. The death-rate among the children is said to be appalling.

Much complaint is being made of the character of the ambulances supplied by the war officials. Their massiveness may be estimated from the fact that it requires twelve mules to draw one over broken ground, although they only accommodate two patients lying down and four sitting up. A patient carried in one of them to the hospital writes that the agony he endured from the jarring of a compound fracture exceeded the setting of it afterward. By contrast with this condition of affairs the Boer ambulances are of the most modern and approved pattern; carry four or even eight patients lying down and are drawn by two horses. One of the private English field-hospitals, however, has a star equipment in this respect. Its ambulances are light road-wagons, can go anywhere and keep up with the movements of the cavalry. It has earned for itself the title of "the galloping hospital."

It is being discovered that the recent detachments of reservists and militiamen forwarded to South Africa contain a very large number of "lame ducks," hopelessly incapable of going to the front. It is quite evident that the examinations at home have been conducted by men who do not understand military requirements, or who were so pressed for time that they could not do thorough work. Cases of distinct phthisis, of renal disease, of well-marked tertiary syphilis, of ulcer of the leg, of large varicose veins, of varicocele, of old inguinal hernia, and similar ailments, have been landed at Cape Town only to be sent back home; and this not in ones and twos, but in a very fair proportion.

Frederick Treves who is with the forces as consulting-surgeon says that the men at the front are a fine, hardy, heroic set. One poor fellow, who had been hit by a piece of shell at Spion Kop, which had carried away his left eye, the left upper jaw and the corresponding part of the cheek, and who was unable to speak, when landed at the hospital made signs that he wanted to write. Pencil and paper were given him with which to express his needs, but he merely wrote, "Did we win?" Of course, no one had the heart to tell him the truth.

SELECTION.

BERIBERI AND PLAGUE AT PORT TOWNSEND QUARANTINE.[1]

By M. HUGH FOSTER, M.D.,
ASSISTANT SURGEON, U. S. M. H. S.

Nothing is so effective in allaying fear and avoiding panic as preliminary and intimate knowledge concerning the possible cause of such conditions. To this end we publish in full the following detailed account of the thorough manner in which the Marine Hospital Service is meeting the threatened invasion of our shores by the bubonic plague.

"I have the honor to make the following re-

[1] Report to Surgeon-General Wyman.

port of the condition of affairs relative to the Japanese steamship 'Nanyo Maru,' now held in quarantine at Port Townsend. This vessel arrived here January 31st, seventy-five days out from Kobe and thirteen days from Honolulu. She gave a history of having carried 312 Japanese immigrants from Kobe to Yokohama, and had been disinfected at Yokohama and detained seven days on account of suspicious glandular enlargement of 3 of her passengers. These cases, according to Sanitary Inspector Eldridge, proved not to be plague and the vessel departed, leaving these 3 behind. There were 800 passengers on board to work in the sugar plantations. I understand that these were held on the vessel for thirty days before they were allowed to land at Honolulu, and as a result the vessel was in a filthy condition when she got here. Two cases of beriberi were discovered—1 among the passengers and 1 among the firemen. On arrival at quarantine these were removed to the hospital and the vessel started to unload her cinder ballast. Two other cases were reported during the afternoon, 1 of whom died during the night.

"The necropsy I reported at length in my letter of February 2d, and it showed all the signs of beriberi, but in addition there was a general glandular enlargement all over the body. This caused me to send some of the glands and a part of the spleen to Surgeon Kinyoun at Angel Island for microscopical examination, and to recommend that the vessel be held pending his report. On February 2d, 1 of the inmates of the hospital died and the necropsy was exactly similar to the first. Two additional cases of beriberi were admitted on this day and 5 on the following, making a total of 11 cases up to that date and 2 deaths. The patients in the hospital all had swollen and edematous legs, more or less paralysis of the limbs, and complained of pain in the muscles and oppression of the heart. The necks and faces of the severer cases were also swollen and there was 1 case of suppression of urine. A personal examination showed me that about half of these had enlarged glands, but none of them has ever had any fever nor have the glands been tender or painful. A large number of the crew and steerage also showed generally enlarged glands, but were well and lively. I took some of the glands of the second case and rubbed them up in a mortar with sterile water and injected 1 c.c. of the solution into the leg of a rabbit. This rabbit is alive and well fifteen days after. Three of the 9 remaining cases looked to be serious, but all have convalesced nicely except 1, who died on February 16th, and presented the same appearances at the post-mortem as the other 2.

"To return to the vessel, the crew were set to work discharging ballast and a preliminary disinfection with sulphur made in the steerage which was the worst part of the entire vessel. The passengers were taken ashore, and, after the usual bath and disinfection of clothing, were put in the barracks. The captain, under coercion, ordered a supply of fresh bread and beef for all hands. A quantity of spoiled food was condemned and burnt. The water-tanks were boiled by turning in steam and a new supply of water given. After three or four days of mechanical cleaning-up by the crew and quarantine attendants, the vessel and crew were disinfected. All were then returned to the vessel. The bathhouse and disinfecting-room were disinfected at the completion of the process, as is our routine custom. The pilot was kept at the station as he had been on board the vessel all night.

"Upon receipt of a telegram from Surgeon Kinyoun that he had found something suspicious, Dr. Seavey was placed in charge of the hospital and a strict quarantine imposed upon him as had been upon the nurse and hospital from the start. The entire station, including surgeon's and attendant's quarters, was disinfected and all the clothing and bedding of the complete personnel sterilized. The antipest serum was sent to the quarantine yesterday, and I have ordered every one on the station and those in the hospital to receive an immunizing dose of 10 c.c., and I think we are taking every precaution possible.

"To sum up, I would state that I have no doubt that all of these cases had beriberi, that the first one was probably recovering from an ambulant case of plague seems possible from the finding of the plague bacillus in the glands, as reported by Dr. Kinyoun. I understand that he was not ashore at Honolulu, and may have received his infection at Kobe, at least seventy-six days before death. I shall, therefore, redisinfect the vessel and permit her to depart with a new crew if the owners desire, but I shall detain the entire personnel fifteen days to await developments; this I regard as very necessary. . . . I have received 24 flasks of the pest serum and ordered 3 antitoxin syringes from Seattle as soon as I received word that it was coming. All we need now is a larger supply of the antipest serum and we will be fully equipped for any emergency."

CORRESPONDENCE.

LEGISLATIVE FADS VERSUS INDIVIDUAL LIBERTY.

To the Editor of the Medical News:

Dear Sir:—In your issue of February 10th, page 228, I notice a news item on medical control of marriages. The item in question informs us that a bill is before the legislature of Colorado, "which, if passed, will place the granting of marriage licenses in that State in the hands of a board of medical examiners."

From the general tenor of the bill, as given in the news item, there is but little doubt in my mind that it was prepared by a medical man. One of the many—alas, too many—whose ambition or spirit is not satisfied with quietly working strictly within the sphere of their chosen calling, but who feel impelled to exercise a despotic control over the individuals who make up that ever-erring,

distract, and sorely abused football of venal and vicious, or ignorant, politicians—the State. Of course, it is all done for the good of humanity! All such, and kindred, statutory enactments—which are being piled up by every legislature of every state, *ad nauseam*—have been established to that end. I hope that the bill will pass the legislature, in order that the Governor, with a severe scoring of its projectors, may veto it because of its patent unconstitutionality.

Such coercive measures for the betterment of social evils, and general improvement of mankind, are fundamentally wrong. "By the pursuit of this absurd policy, modern reformers, forgetting that they are following in the footsteps of the old French despots, imagine that they are hastening the millennium. What they are hastening is only a revolt against their suppression of freedom. They are building up a despotism of democracy certain to become just as hateful and intolerable as the despotism of autocracy."

To all would-be hasteners of the millennium, to coercive-philanthropy advocates, and to those who feel irresistibly impelled to frame, and lobby through the legislature, laws which are intended to improve mankind physically and morally, I would commend the study of Von Humboldt, Huxley and Spencer.

Albert F. Fuchs, M.D.

Loyal, Wis., February 26, 1900.

EGG-MEMBRANE FOR SKIN-GRAFTING.

To the Editor of the MEDICAL NEWS:

DEAR SIR:—I notice in your journal of January 27th, under the heading of "Echoes and News," that the lining membrane of the egg was used the first time in the United States for grafting purposes at the Methodist Episcopal (Seney) Hospital, Brooklyn.

This is not so unless tried more than three years ago, as I used egg membrane successfully for grafting during my service as intern in the City Hospital, during 1897 and 1898.

There was a case of an extensive burn on the body admitted to Ward VIII., that refused an operation for skin-grafting; consequently the membranes of the ordinary hospital eggs were used, but with little idea of success on account of the uncertain age of the eggs. The membranes were applied and treated in the same way as the ordinary Thiersch grafts. On the fourth day the bandage was removed and the wound washed with normal saline solution. All of the membrane seemed to come away, but close inspection revealed the fact that small parts of the inner layer of the egg membrane were adherent, forming minute bluish islands on the granulating surface of the wound. These islands gradually spread over the whole raw surface covering it with a bluish-red skin.

I found the growth of the egg membrane grafts much slower than that of the old skin method, but otherwise satisfactory. Two cases have been treated since with the same results.

I do not think my case was the first treated in this way in America, as the idea was obtained from some medical journal.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, March 3, 1900.

SIR JAMES PAGET'S ESTATE—SMALL DISEASE-RATE AMONG TROOPS IN SOUTH AFRICA—NATURE OF "CAMP-FEVER"—THE CORYZA OF THE TROPICS—A HISTORIC INSTANCE OF HAIR TURNING WHITE UNDER EMOTION EXPLODED.

IN these days when the wicked flourish as a green bay-tree and we are assured that it is chiefly the charlatans in the profession who succeed financially, it is a comfort to come upon instances of genuine merit reaping rewards not merely of fame but of substantial emoluments. The case in point is furnished by the publication of the will of the late Sir James Paget. His net estate reaches the by no means imposing but most comfortable figure of $370,000, which is divided almost equally among his six children. There is a custom among the leading newspapers here which strikes an American curiously, in spite of our alleged utter journalistic indifference to the rights of individual privacy, of going to the public register of wills filed for probate, picking such as will be of interest to the public, either on account of the man or the amount, and publishing them in outline, but often with a full list of the bequests. When it is remembered that Sir James Paget began his career in London almost penniless and supported himself for several years upon a perilously slender income of barely $400 a year, won by writing and coaching, and that he always worked from sheer love of his work and for fame, rather than for money, the accumulation of such a sum is really remarkable, and goes far to rehabilitate temporarily the now exploded superstition that virtue is its own reward.

The losses by disease of the troops in South Africa still continue remarkably low, considering that they include those of three hot-besieged and closely beleaguered towns, with a total of some 15,000 men cooped up in them. The total deaths to date from disease are barely over 600, as contrasted with 1400 from wounds, making less than one-third of the total mortality. Six hundred deaths in five months among an army ranging from 80,000 to 150,000 men makes a death-rate, roughly speaking, of only about 15 per 1000 per annum, lower than that of most cities in times of peace and only about treble the ordinary barrack rate. For almost exactly half of this number typhoid is responsible, and this mainly in Ladysmith, where it was endemic before the siege began and the water-supply badly polluted. For a time the typhoid death-rate steadily increased, but

it was fought so vigorously by the medical officers and sanitary precautions so rigidly carried out that we now have the cheering news of its rapid abatement. The same is true of dysentery, and although that indefinable and irritatingly indefinite disease "camp-fever" is slightly increasing, this is fortunately of a very mild type.

Several tropical practitioners have attempted to explain this mysterious disease during the past few weeks and the sum and substance of their statements appears to be that in the tropics, for some reason, a rise of temperature with furred tongue, headache and enteric catarrh, lasting for several days occurs very readily. The fever is clearly neither typhoid nor malaria and seems to correspond to the old "simple, continued fever" of our earlier text-books. It is possibly the tropical equivalent of our northern coryza, which is comparatively rare in hot climates; at all events, it seems to be a disease against which no preventive measures can be taken, as its origin is quite unknown.

To succeed in stamping out an already established epidemic of typhoid, in a besieged town, with a polluted water-supply, and in the height of an African summer, is certainly a triumph of modern medicine and one upon which the medical men, both army and civilian, of Ladysmith are to be warmly congratulated.

The death of Mr. Joseph Cowen, the Newcastle millionaire-statesman, has brought to light a curious little incident of some medical interest. Cowen in his younger days was an ardent revolutionary sympathizer, and his house was the hospitable refuge of half the conspirators of Europe, among them Orsini, who threw the bomb at Napoleon III., and killed more than a score of people. When Orsini was arrested for the crime his beard was jet black, but during his trial and condemnation it turned snowy white, and the change was set down as an instance of a man's hair turning white under intense emotional strain. It just so happened, however, that Orsini, on his last visit to Cowen's house, only a few weeks before his attempt, had accidentally revealed the fact that *his beard was dyed*. Hence, the change of color during his trial was simply the fading out of the dye in prison, where he had no means of renewing it. Mr. Cowen was fond of relating the story, and it well illustrates the caution with which even historical accounts of the occurrence of this remarkable change should be accepted as genuine. There seems little question that this dramatic change "and his hair turned white in a single night," does occur, but probably with scarcely a fifth of the frequency with which it is credited.

PARACECAL LESIONS SIMULATING APPENDICITIS—SUBACUTE TETANUS SUCCESSFULLY TREATED BY INJECTIONS OF SERUM COMBINED WITH TREATMENT BY CHLORAL—DEATH FROM EATING PATE DE FOIS GRAS—PRURIGO GESTATIONIS.

At the Society of Surgery, January 24th, Gerard-Marchant mentioned three instances in which he had operated expecting to find an inflamed appendix, but had found instead one or more enlarged glands lying in front of the cecum. He insisted on the distinct etiology in such cases, considering the trouble to be of tubercular nature, although the examination of the removed glands had failed to show the usual tubercular lesions in them.

Jalaguier mentioned a similar case occurring in his own practice. Although the appendix appeared perfectly healthy, he nevertheless inclined to the idea that it was the cause of the glandular enlargement and that the inflammation in the appendix had subsided before operation was performed, while the secondary inflammation in the lymphatic glands situated at the ileocecal junction had persisted.

Quenu said that the term *para-appendicitis* sufficiently describes a group of inflammations occurring around the termination of the ileum and the cecum. He had observed several instances similar to those mentioned by Gerard-Marchant. In one patient who had been taken suddenly ill with the symptoms of a severe attack of appendicitis he found an appendix merely congested, while the surface of the cecum was covered with fibrinous exudate containing streptococci and coli bacilli. A very careful histological examination of the appendix failed to show any lesions whatever. Other surgeons have reported cases of ulcerative typhlitis without any appendicular lesions. The symptoms being those of ordinary appendicitis.

The discussion upon para-appendicitis was continued at the meeting of February 7th. Nimier referred to two cases of inflammation of the omentum which had been taken for appendicitis. There was presumably a relation between the epiploitis and the appendix, the appendix in his case seeming to be the starting-point for the infection.

Bazy called attention in 1805 to the part played by the cecum in inflammations in that region, but his views did not receive much consideration. Since that time many observations have been made in support of them. He mentioned one in which a girl of seventeen years entered the hospital with a tumor in the right iliac fossa. Operation revealed a mass of inflamed retrocolic glands, but no appendical lesion. In another case, an abscess was three times opened in the groin and once in the hypochrondrium, the starting-point of which was afterward proved to be the appendix.

ALBARRAN once operated for gangrenous appendicitis and found in addition to the appendical lesions two gangrenous plaques upon the cecum, although the appendix was quite a little distance removed from them. In another case the posterior wall of the ileum was the seat of a very virulent inflammation, while the lesions of the appendix were of a slight degree only. These patients had presented the usual symptoms of appendicitis.

At the session of February 14th ROUTIER related the details of a case of abscess of the spleen consecutive to an appendicitis. It is not surprising that an appendicitis like other infective processes can produce abscesses at a distance. This is a different matter from cases of inflammation of the cecum in which the appendix is not involved. And yet those who have reported such cases have usually mentioned the fact that the appendix was somewhat inflamed, and in all probability it was the starting-point of the inflammation which in the cecum or ileum or paracecal glands became more violent. Too much stress should not be laid upon such variations from the normal type.

QUENU again affirmed his opinion that the facts mentioned were indisputable and deserved recognition. There are certainly lesions in the neighborhood of the cecum which develop independently of the appendix; at least one is justified in saying so, when the histologic examination of that organ shows that there is no erosion of the mucous membrane, and no lesion of the follicles.

REYNIER mentioned an instance in which he had cut down upon what he supposed was an appendicular abscess, and found that the appendix was not involved, but that the source of the pus was a mass of broken-down glands. In another patient, with symptoms of appendicitis, the lesion was found at operation to be a ureteritis.

DELBET said that he had once found a perforation of the cecum about 3 cm. (1.2 in.) from the base of the appendix. The symptoms were those of rapidly spreading peritonitis. The advantage of the term para-appendicitis is a questionable one. For his part he does not see why lesions which have nothing to do with the appendix should be called para-appendical.

At the Medical Society of the Hospitals, February 2d, PETIT spoke of the cure of two patients suffering from subacute tetanus, by the injection of antitetanic serum, and the administration of large doses of chloral. One patient who worked in a slaughter-house was wounded in the thumb. One week later he experienced pain and contractions in his arms, followed by trismus, opisthotonus and contractions of the muscles of the limbs and thorax. He was given one injection of antitetanic serum daily, and from 12 to 18 grains (3 to 4.5 drams) of chloral. A second patient, who was wounded by a plank in the scalp, and who did not develop symptoms for three weeks, was treated in the same manner. Both of these patients recovered, the first having received 590 c.c. (20 oz.) of serum in 21 days, and the second 560 c.c. (19 oz.) in 17 days.

MERKLEN and RENDU also mentioned cases in which the plan of treatment described had been followed by recovery.

VAQUEZ related a case in which small doses of the serum had failed to avert death, and said he considered that a fatal end might have been prevented had much larger injections been employed.

At the session of February 16th PAPILLON described the results of an autopsy upon a man who had died as the result of eating spoiled pâté de fois gras. Soon after the meal anurticaria broke out, followed by symptoms similar to those seen in cholera. The most important lesions were found in the liver and kidneys. In the former there were foci of parenchymatous hepatitis and an infiltration of yellow pigment into the hepatic cells. This pigmentation, probably of hemic origin, ought to direct attention to the blood in cases of alimentary poisoning. The epithelium of the kidneys was almost entirely necrotic, and the appearances presented by the organs were almost identical with those produced by virulent microbic toxins.

At the Society of Dermatology and Syphilography, February 1st, GASTOU showed a pregnant woman whose forearms were the seat of a well-marked prurigo. This affection recurred with each pregnancy and disappeared entirely in the intervals between them. The lesions were solely papular and recalled those of a parasitic prurigo. Prurigo gestationis is due to an autointoxication, as shown by the decrease in urea, chlorides and phosphates, and the presence of pigments in the urine. In selecting the treatment the doctor should bear this fact in mind. The patient should be kept in bed, and the utero-ovarian difficulties which so often precede the prurigo of gestation should also be treated.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.—SECTION ON MEDICINE.

Stated Meeting, Held Tuesday, February 20, 1900.

John H. Huddleston, M.D., Chairman.

Lymphocytes in Typhoid Fever.—Dr. A. H. Gardiner read a paper in which he detailed his observations on the blood of typhoid fever patients and also those suffering from other diseases. His conclusions with regard to typhoid are as follows: Only very exceptionally does leucocytosis occur during the course of typhoid fever. Practically always there are fewer eosinophiles than normal in the blood of typhoid fever patients. Among the leucocytes the lymphocytes exceed in number the polynuclear white blood cells. The small lymphocytes exceed the large lymphocytes in number.

In discussion Dr. Adler said that the counting

of the blood in detail as has been done by Dr. Gardiner would probably give us important data on the pathology and physiology of the blood. A number of important questions with regard to the blood are as yet undecided. It is not definitely known that lymphocytes give rise to the polynuclear leucocytes, nor is it clear where either of these forms of cells originates. Studies so far undertaken seem to indicate that the importance at present attached to phagocytosis is too great. Leucocytosis is not a reaction of the system for the elimination of irritants, but is a renewed activity of blood-making organs of white blood cells usually indicating a speedy return to health.

Membranous Colitis.—Dr. William H. Thomson read a paper on this subject. It will appear in a later issue.

Amœbic Colitis.—Dr. H. R. A. Graser made a report on three cases of amœbic colitis. One of them was a hotel-keeper, aged thirty years, who had never been out of New York City. He was having four to six rather liquid stools a day, foul-smelling, streaked with blood and containing a good deal of mucus. He had lost thirty pounds in weight, was suffering from night-sweats, although he had no cough and had never had any. His temperature and pulse were normal. He was treated by the mouth with resorcin for some days and improved so much that he considered himself cured. It was not long, however, before all his old symptoms recurred. Amœbæ were found very plentifully in his stools and he was put on appropriate treatment.

The second case was of a machinist, who had never been farther from New York than Staten Island. He, too, had lost considerable flesh and was suffering from frequent, foul-smelling, bloody and mucous stools. His abdomen was tender to the touch and he had considerable tympanites. Amœbæ were found in his stools. The third case had traveled in the tropics. In this case Charcot-Leyden crystals were found in the stools, as well as plentiful amœbæ. Others have reported these crystals as occurring in the stools in amœbic colitis.

The best treatment is calomel internally in divided doses continued for a number of days. Quinine seems to be the best local treatment. After an injection of quinine it is usual to find the amœbæ motionless.

It is extremely difficult with any certainty to recognize dead amœbæ in the stools. The stools should be received in warm vessels and should be examined as soon as possible on the warm stage of the microscope. The parasites will then usually be found in the mucous material on the surface of the fecal masses or in the midst of mucous bodies that occur here and there in the stools. Whether these parasites are really pathogenic or not is an open question. Experimentation on animals has not thus far succeeded in demonstrating their pathogeneity with any assurance.

There seems to be no doubt, however, that we have in temperate climates, and especially here in New York, an endemic colitis seemingly due to the amœbæ, or at least always accompanied by the presence of this parasite in the stools. The subject is deserving of further careful investigation.

Dr. H. Brooks reported eight cases of the disease from the fourth service of Bellevue Hospital. Four cases also were noted in private practice. The disease is evidently not rare in New York and is endemic. In six of the cases the infection seems to have taken place outside of New York City, but two of the patients were certainly infected here. The characteristic symptom of the disease is the presence of crampy muscular pains in connection with frequent ill-smelling stools. Cramp in the calves is especially noted. So much so that it has almost become the rule to look for amœbæ if a patient comes into the hospital complaining of cramps in the calves and increased frequency of stools.

Technic for Detection of Amœbæ.—It is very necessary if the amœbæ are to be kept active that the stools should not be allowed to become cold. For this purpose the bedpan should be kept warm. If the stools are acid when passed the acidity should be neutralized with sodium bicarbonate.

The slide on which the specimen is examined should be warm. Even after apparent death they may be aroused into activity by warmth. In the tissues the best stain is thionine. The intensity of the colitis is in direct proportion to the number of amœbæ that are present. Quinine renders the parasites non-motile.

Prognosis of Colitis.—Dr. Crooks said that the prognosis of the chronic form of colitis depends a good deal on the lesions that accompany the disease. For prognosis careful diagnosis is also necessary. Cirrhosis of the liver and Bright's disease, besides other constitutional conditions, sometimes gave rise to, or favor the progress of, a colitis and necessarily make the prognosis very unfavorable. For tubercular and carcinomatous colitis the prognosis is that of the underlying disease. Chronic dysentery as a rule is the opprobrium medicorum and it has not lost its terrors even with all our modern methods of treatment.

Treatment.—Dr. Kemp's tube for colonic injections was presented and described. The instrument should be introduced with a rotary movement, and if the flow stops the tube should be rotated until the flow is free again. If the outflow-tube becomes blocked the end of the tube attached to the syringe should be fastened to it so as to clear it out. The water should be allowed to flow back in a steady stream and not by gushes as there is some danger of injuring the mucous membrane at the end of the tube should it be sucked into the openings. The outflow may be made rebular by slight pressure on the outflow tube, the pressure being regulated according to the height of the injection desired.

Dr. Morris said that there are two conditions which by interference with the intestine may give rise to mucous or membranous colitis. A floating

kidney, for instance, may so interfere with the colon as to cause a functional disorder. Enteroptosis is liable to produce the same effect.

Dr. Franklin said that in Central America, where colitis is quite common, internal medication is usually considered to do no good and local medication alone is employed. Where milder solutions do no good strong solutions are frequently employed. An injection of four ounces of nitrate of silver solution, of the strength of ten to twenty-five grains to the ounce, is sometimes employed with success where weaker solutions are ineffective. Morphine must be given some time before the injection in order to allow its retention. Since employing these strong solutions in very severe cases, Dr. Franklin has not lost a case and he has a good deal of confidence in this method of treatment. Despite its severity patients who have been benefited by this method once asked for it again. Quinine by injections has been found to do good, but is not so effective.

Amœbic Dysentery in Animals.—Dr. Graser mentioned the fact that Professor Quincke had recently published a series of observations on the effect of amœbæ on animals. He had found that there were two forms of the amœba, the *amœba mitis* and the *amœba fellis*. The amœba mitis or mild form is obtained from patients suffering from the endemic colitis of temperate climates. This form of the parasite is not pathogenic for cats. Large quantities of the stools from such patients may be injected into the intestines of cats without producing dysentery. The amœba fellis, on the contrary, is pathogenic for cats. It is obtained from patients suffering from amœbic colitis acquired in the tropics. This form of the amœba may be readily recognized by the fact that red blood-cells are found within it. When injected into cats this organism produces frequent bloody and mucous stools and finally leads to a fatal termination.

Dr. Adler said that in cases of dysentery admitted to the German Hospital the stools are always examined for amœbæ. Protozoic dysentery is much commoner than has been thought. The fauna and flora of the intestinal tract are not well known. It has become a text-book dogma that amœbic dysentery occurs only in the tropics. There is no doubt, however, that there is an endemic form of a protozoic dysentery here in New York. The amœbæ that occur on the Isthmus of Panama and in Egypt are very different from those found in the stools of patients who have never been outside the temperate zone. The endemic form of dysentery is not difficult to treat. Relief of symptoms is, however, much more frequet than permanent cure. Even after well-formed stools have been occurring for some time, amœbæ may be found in them. This is the secret of the frequent recurrences which take place. The best internal antiseptic is undoubtedly calomel. It invariably kills the amœbæ. None of the other intestinal antiseptics are as efficient. Salol, dermatol and tannalbin have been tried but without the good results obtained from calomel.

THE NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held Monday, February 19, 1900.

The President, Frederick Holme Wiggin, M.D., in the Chair.

The subject of the evening was a discussion on anesthetics.

Selection of the Anesthetic.—Dr. John A. Wyeth said that no one anesthetic was the most desirable for all cases. The anesthetic should be selected with due regard to the condition of each patient. No matter what the anesthetic, less of it will be required if morphine is given some time before. Chloroform has many advantages as an anesthetic, but the heart should be watched very carefully during its administration. Mere rapidity of pulse makes very little difference, but if cardiac irregularity develops the chloroform should be removed for a time at least, to see whether or not reaction to normal takes place promptly. If great pallor of the face develops the patient's head should be allowed to sink back below the level of the body, or the patient should be put in the Trendelenburg position. It is preferable to operate always on a table on which the patient may be readily put in this position. If the irregularity of the heart continues, or if other symptoms show that the patient resents chloroform after a careful trial, the anesthesia should be continued with ether. If there is any kidney trouble, after a few minutes of ether anesthesia chloroform may be resumed. The difference in the irritant effects on diseased kidneys of the two anesthetics is enough to justify one in trying every possible means to administer chloroform provided it can be done without serious danger to the patient. The greatest precautions will be required, however, and these cases demand a skilled anesthetist. If at any time during the administration of an anesthetic the pupils should suddenly dilate, the anesthetic must be stopped at once for some time. One of the great dangers of anesthesia is the bringing of patients under the influence of an anesthetic too suddenly. Fifteen or twenty minutes should be taken at least to bring a patient quietly under the influence of chloroform. Ether should not be administered through an open inhaler. The Allis instrument, for instance, is extremely objectionable because the air that is inspired is lowered greatly in temperature by the evaporation of the ether, and is carried directly into the lungs, where it is sure to be a source of serious irritation. Within the closed inhaler, as for instance the Ormsby apparatus, the air is continually reinspired and kept at a uniform temperature not very far from the temperature of the body, and the reinspired air produces a modified asphyxia which aids the ether in the production and maintenance of the anesthesia. This asphyxia can be controlled as well as any form of anesthesia, and is of great help. Where the closed inhaler is used patients

come out from under the influence of the anesthetic sooner, there is apt to be less vomiting, and there is considerably less irritation of the respiratory passages than when the anesthesia is conducted by the open method. Considerably less ether is used by this method, and where there already exists any chronic inflammatory condition of the air passages, or any chronic nephritis, the irritation is proportionately less than by the other method.

Safety of Anesthetic.—For the tyro in the administration of an anesthetic, ether, as a general rule, is probably safer than chloroform. For the expert anesthetist chloroform is at least as safe. Where kidney trouble exists chloroform is to be preferred. Where chronic tuberculosis of the lungs is known to be present, or where chronic bronchitis exists, chloroform usually gives the best satisfaction. There are many who prefer ether where the heart is crippled. For abdominal operations chloroform is the best, because it produces less tendency to vomiting afterward. It should always be employed if the heart is not involved and its compensation seriously interfered with by chronic valvulitis or endocarditis. There is considerable danger in the use of chloroform after repeated attacks of rheumatism, or where arteriosclerosis exists or fatty degeneration is suspected. For alcoholic patients, as a rule, chloroform is preferable, because ether must be employed in very large quantities and even then may be ineffective. For children ether is the better anesthetic, although the text-books as a rule teach differently. Within the last few years Dr. Wyeth has seen three deaths in children under twelve from the use of chloroform where only minimum amounts of the anesthetic were employed. There is danger especially with poorly nourished children and those that are very much frightened by the anesthetic and struggle against its use. The anesthetic should not be forced on children if possible, but they should be persuaded into gradually coming under its influence.

Amount of the Anesthetic.—Dr. Thomas L. Bennett said that most of the dangers of anesthesia come from the use of more of the anesthetic than is absolutely necessary for the production of the condition of insensibility necessary for operative procedures. The amount of the anesthetic, no matter which one it may be, bears a direct proportion to the amount of shock, exhaustion, pulmonary edema, pneumonia, or nephritis that develops after the anesthesia. Ether is the most irritant of the anesthetics, must be used in larger amount and gives rise to most nausea and vomiting. Bronchial pneumonia is a complex affection, but is mainly due to the anesthetic. The aspiration of saliva in large quantities into the pharynx and from here into the lungs cannot but prove a source of infection. The pneumococcus exists very often in the mouth and is thus often drawn into the lungs, setting up an inflammation. In patients whose kidneys are affected before the operation, just as little as possible of the anesthetic should be used. About the age of puberty many children require a large amount of an anesthetic. The same is true for drinkers and for many nervous people. Certain operations require that the patient should be more deeply under the influence of an anesthetic and so necessitate an increase of the amount to be used. All operations on the rectum, on the urethra, and the perineum are of this kind. The amount of an anesthetic to be used in any given case depends to a large extent on the anesthetist. A skilled anesthetist will use must less than one who is unused to the administration of anesthetics. In 65 New York Hospital cases in which the amount of anesthetic and the length of the operation were carefully noted, 3732 minutes of anesthesia required 275 ounces of ether. The average length of the operation was 57 minutes, and the average amount of ether required was 4¼ ounces. As a general rule it may be said that about 4 ounces of ether will be required for the first hour of anesthesia and about 2 ounces for the second hour. Of chloroform about an ounce per hour will be required.

Nitrous Oxide for Long Operations.—Dr. S. Ormonde Goldan read a paper on the use of nitrous oxide and its modifications by mixture with carbon dioxide or pure oxygen for prolonged surgical operations. For a long time it was thought that nitrous oxide could not be used for anything but short operations, such surgical procedures as could be accomplished between the time of the removal of the anesthetic and the coming to of the patient. Of late, however, it has been found that where other anesthetics are contraindicated, nitrous oxide can be used even for lengthy operations. In abdominal operations it is often urged that nitrous oxide fails to produce relaxation of the abdominal walls. If the legs are flexed, however, the abdomen becomes thoroughly flaccid. Vaginal examinations can be accomplished in this way very satisfactorily under nitrous oxide anesthesia. For gynecological operations the failure to obtain complete relaxation of the abdominal walls is sometimes annoying. Nitrous oxide may be used until the incision of the peritoneum and then ether substituted. Nitrous oxide combined with carbon dioxide has certain advantages. There is apt to be less headache after the anesthesia than when nitrous oxide is used alone. Nitrous oxide is combined with oxygen to prevent cyanosis. It is often very difficult, however, to obtain complete anesthesia with this combination and great skill is required in the administration of the anesthetic. Some patients cannot be brought sufficiently under its influence to dull their sensibilities properly for surgical procedures. As a general rule it may be said that nitrous oxide is not more expensive than the other anesthetics. It has many advantages, especially for the beginning of anesthesia, and is less expensive than ether.

Ethyl Chloride as a General Anesthetic.—Dr. James P. Tuttle detailed his experience with this substance as a general anesthetic in 40 cases. He used the ethyl chloride for the beginning of the

anesthesia and then substituted ether. He is able to produce insensibility in this way in from two to seven minutes. The ethyl chloride is sprayed on the lower surface of an Esmarch inhaler and given as ether is, then an Ormsby inhaler is used to continue the anesthesia with ether. There is no nausea nor vomiting after the anesthesia, and in only four cases was there failure to secure prompt insensibility to pain. In two the result was unsatisfactory. One of them was an anemic patient in whom the ethyl chloride did not take effect for twenty-five minutes and ether had to be substituted. In the other case after fifteen minutes of ethyl chloride ether was substituted, but in neither of these cases did the previous administration of the ethyl chloride seem to retard the effect of the ether. Two other patients, although susceptible to the ethyl chloride, proved absolutely insusceptible to the ether, and chloroform had to be administered to them. As a rule about ten to twenty c.c. of ethyl chloride were employed.

Complicated Inhalers.—Dr. Hobart Amory Hare of Philadelphia, present by invitation, opened the discussion. He said that the fad for complicated inhalers had come from London. Personally he is opposed to cumbersome apparatus which have no distinct advantage and have many decided disadvantages. The tube of the nursing-bottle is a good example. The new-fangled inhalers undoubtedly may prove as fruitful a source of infection and of pulmonary accidents as the fatal nursing-tube. For some of them sterilization is practically impossible because infinite precautions would be required. He is happy to say that the surgeons in Philadelphia seem to be perfectly satisfied with the simplest form of inhaler. Ether is probably the safest anesthetic, but it should be given with as much fresh air as is compatible with anesthesia. When ether is given by the closed method other factors enter into the result. The carbon dioxide from the unexpired air produces a certain amount of asphyxia and the patient is benumbed by the organic material which exists in the expired air and is reinspired. We now know that the danger of rebreathing air is not so much because of the larger percentage of carbon dioxide which it contains as because of the organic material thrown off from the lungs and which exists in the expired air in dangerous amount. This causes the heavy, drowsy feeling that occurs in badly ventilated rooms and is the source of the headache and nausea which is so often complained of when people remain for long periods in air that is not changed often enough. Bag inhalers seem unnecessary and unwise. There is too much routine in the giving of an anesthetic. A man accustomed to ether always gives ether; one accustomed to chloroform, always chloroform. The anesthetic should be selected according to the condition of the patient. Where the kidneys are affected chloroform is preferable to ether. It is surprising to hear Dr. Wyeth declare that chloroform is more dangerous for children than ether. Ether is certainly objectionable because it is more irritating to the delicate mucous membrane of the child and easily gives rise to capillary bronchitis. Fright is an important element in anesthesia in children and it is avoided to a great extent by the use of chloroform.

Vasomotors in Anesthesia.—The danger in giving an anesthetic seems to be mainly due to interference with the vasomotor mechanism. The patient may bleed to death in to his own blood-vessels. It is vasomotor palsy, not heart failure, that causes death. Dentists, who administer ether to their patients in an erect posture have more deaths during anesthesia, proportionately, than surgeons who administer it to recumbent patients. In a gynecological operation not long ago, the patient became pulseless, no apex beat could be felt and the heart was beating extremely irregularly and weakly. The ordinary measures did not revive the patient and a fatal termination seemed imminent. The abdomen was already open, and Dr. Hare suggested that the operator should grasp the abdominal aorta and compress it. This confined the circulation to the upper part of the trunk and head, and the patient began at once to revive. A similar attack happened a little later and again the patient was revived by this means. The vasomotor system is just as important as the heart, and a surgeon should be assured of its condition before anesthesia. Atropine is often recommended for its good effects during anesthesia, especially when chloroform is used, and the reason seems to be because it is a good vasomotor stimulant. An excellent precaution in very weak patients would be to apply an Esmarch bandage to the arms and legs and even a compress to the abdomen before anesthesia in order to made the blood stay in the head and thorax. Finally, it is to be remembered that the amount of an anesthetic given for the production of anesthesia in any given case depends to a large extent on the anesthetizer. If he is skilful much less can be used.

Precautions in Anesthesia.—It is sometimes said that the head of the patient should be well extended, hanging somewhat backward, because in this position the epiglottis is pulled forward. In this position, however, the soft palate presses down upon the tongue and makes breathing through the mouth difficult. If the head is put forward in the position assumed by athletes in running, the epiglottis is raised just as effectually as before and the soft palate does not press down upon the tongue. This position may be secured by turning the patient's head to one side. With the fingers to keep the jaw well forward and the head in this position, tongue forceps will not be needed as a rule and sore tongues will be avoided.

Morphine administered before the anesthesia often lessens the vomiting. If given with $^1/_{200}$ to $^1/_{100}$ of nitroglycerin there will often be no vomiting at all. Nitrous oxide is dangerous where atheroma exists. It is always a dangerous anesthetic in advanced life. Dr. Hare has seen a death from hemorrhagic apoplexy in a dentist's chair after nitrous oxide anesthesia.

Anesthetics and the Kidneys.—Dr. Kemp said that the safest anesthetic, as far as irritation of the kidneys is concerned, is nitrous oxide mixed with oxygen. Where patients are old, however, and atheromatous conditions exist, nitrous oxide is contraindicated. Chloroform comes next in order in its lack of irritation of the kidneys. Ether is last and worst. Ether should always be administered after preliminary anesthesia with nitrous oxide. The A.C.E. mixtures and Schleich's mixture possess no advantages over the simple anesthetics so far as regards the irritation of the kidneys and they have all disadvantages of the separate constituents.

Safety of Nitrous Oxide.—Dr. Hasbrouck, a dentist, said that he has administered nitrous oxide some 95,000 times during the last forty years without a single fatal result. Patients go under the anesthetic almost imperceptibly to themselves and with a feeling of pleasure, not discomfort, if the anesthetic is properly administered. In over 500 cases he has administered the anesthetic for over an hour. Only in very exceptional cases is there an idiosyncrasy for nitrous oxide which makes its use as an anesthetic impossible. It is important for successful anesthesia that the tubes leading to the inhaler mask should be of good size. As a rule they are made too small and the gas is not supplied fast enough to maintain anesthesia. The tubes should be at least as large as the human trachea and should not be closed by cumbersome valvular mechanism.

Chloroform vs. Ether Mortality.—Dr. Dawbarn said the trend of Dr. Hare's remarks had been something of a surprise and he would devote his five minutes to a partial reply. Dr. Hare had strongly disapproved of the air-bag inhalers for ether, and advised adhering to the use of the towel-and-paper cone, or to the Allis inhaler. Also, by his obviously strong approval of the Philadelphia use of ether only, and disparagement of chloroform, he invited inevitable and unfortunate comparison with other cities. In London, New York, and many other surgical centers it is now understood that the Clover air-bag principle is by far safer than the towel-and-paper, or Allis or other open contrivances. This safety is due to the fact that the ether is rebreathed and promptly warmed up—thus avoiding ether pneumonia, due to chilling the lungs. The carbon dioxide anesthesia which meanwhile is added is a safe form and, as Dr. H. C. Wood has pointed out, is not objectionable. In addition, the closed-bag principle permits anesthesia with very little ether and consequently the kidneys and other organs are much less irritated. Dr. Hare's assertion that as much ether is actually taken up and held in the body by the closed bag as by the open method is plainly seen to be absurd, when we remember that by the latter plan the ether smell can always be noted for at least twenty-four hours upon the breath; while by the former method its odor disappears several hours earlier.

The famous von Nussbaum stated that he had in his long experience used, or seen used, chloroform forty thousand times without a death. And if this be true, a death from this cause implies improper training as an anesthetist. On the other hand, we have the recent and startling statement by Dr. Kemp, with Prof. Thomson, President of the Academy of Medicine, and published in the *New York Medical Journal* to the effect that his study of the vital statistics for a year past in one of the largest and best of the New York hospitals showed one death in each nineteen operations, from ether suppression of urine, *post-operationem*, where the urine beforehand had been tested and found normal! This is a frightful statement. Towel-and-newspaper cones and Allis inhalers were used during this period—and seem responsible for such soaking of the kidneys with ether. It seems likely that a closer study of death-causes in all hospitals would surprise the profession in this regard. Since that time Dr. Kemp has made a similar investigation in a second large hospital, with a practically identical result. It seems fair to say that when at an Academy meeting Dr. Kemp made the above statement, a surgeon of the hospital arose and denied the accuracy; whereupon Dr. Kemp was ready with all the data, the name, page of history-book, date, etc., and no more rebuttal against him was ventured.

I think it is something of a disgrace to our profession that now, some sixty years after the introduction of anesthesia, there should be a difference possible as to the wisdom of using, prior to major anesthesia, alcohol, and a little morphine guarded by atropine. For many years past this has been a routine plan; and to it, as much as to the closed bag in ether cases, is attributed the patient's invariable safety from anesthesia death. There are two or three reasons for this practice: First, all these drugs are analgesic; hence less ether or chloroform will be needed; hence less danger of poisoning from them. Again, all these drugs are supportive to the heart, and tend to prevent shock; the atropine is an excellent vasotonic stimulant—as Dr. Hare also agrees—and finally, but by no means least important, a patient so prepared goes to the table in quite a calm, almost cheery frame of mind, instead of one of agitation and fright.

If, as Dr. Hare has said, this fright deals death to the high-bred dogs subjected to the knife, how much greater is such terror a factor among human beings! We ought never to forget this. It is a most important cause of deaths during the early stages of anesthesia; perhaps is even the chief factor; and to make our patients calm and courageous is to add greatly to their safety while being anesthetized.

Ether and Suppression of Urine.—Dr. Bodine recalled the fact that Professor A. H. Smith had found on mixing acid, urine and ether that a gelatinous material resulted. It is perhaps the formation of this gelatinous material in the kidney tubules that causes their mechanical occlusion and so leads to suppression of urine. This gelatinous product does not result if the urine is

alkaline. It is well, then, before the administration of ether as an anesthetic to make the urine alkaline. There is no doubt that some people are made much less resistant to the shock of operation by the fright which they feel at the prospect of the operation. It has often been noted that people who suffer from a severe accident, which they foresaw for an appreciable time before it occurred, suffer much more from shock than, for instance, those who get hurt in sleeping-car accidents and who consequently have no chance to anticipate the danger. A preliminary dose of morphine allays this fright and so makes the anesthetic safer. In obstetrics there is no fright; the pain to come is looked on as only natural. Hence the better statistics of anesthetics in obstetrical practice.

Schleich's Mixture.—Dr. Maduro insisted that much of the unpopularity of Schleich's mixture is due to the objections of those who have had no practical experience with it. In a large number of cases the mixture has been used successfully and no deaths have been reported from its use. The serious symptoms which develop are not as alarming as those of chloroform or ether, and it is always easier to restore the patient. Meltzer disagrees completely with Schleich's observation in the matter of the effect of the anesthetic. It is a question of the authority of either investigator, but the subsequent observations made by Meltzer do not invalidate Schleich's original conclusion.

In concluding the discussion Dr. Hare said that it was not so much the amount of ether used as the amount of irritation it produced that harmed the patient. In the closed inhaler ether is breathed and rebreathed a number of times; naturally, less ether is used than by the open method. But if one ounce of ether is rebreathed ten times it produces as much irritation as ten ounces of ether breathed but once. With regard to the safety of anesthetics during parturition it must be remembered that pain is a stimulant to the vasomotor system and, consequently, there is less danger in anesthesia while labor-pains are in progress. As Professor Wood's opinion had been quoted in the present discussion, and as one of the speakers had insisted that the question of anesthesia was for the surgeon and not for the medical man who knows the theory but not the practice of the subject, he begged leave to be allowed to quote another of his Philadelphia colleague's expressions. When asked on the witness-stand what was the difference between a physician and a surgeon, Professor Wood said: "A physician is a man who works with his brain; a surgeon one who works with his hands."

REVIEWS.

Transactions of the Luzerne County Medical Society for the year 1899. Published by the Society, 1900.

We have before us a very neatly compiled and bound number for the year 1899, which does credit to the editors and authors. Chief among the articles is one on cancrum oris with a description of the condition, written by Dr. James Brooks. He cites a case of recovery from this condition after a plastic operation had been performed. An article on cancer well merits the perusal of the reader, and the author's conclusions are well in accord with the most advanced theories on this topic. Dr. Wm. G. Weaver, the writer of the article, states that (1) cancer is a disease produced by a parasite; and is a communicable or infectious disease; (2) the hereditary idea of the production of cancer is no longer tenable; (3) cancer being an infectious disease, all the usual precautions against infection should be observed; (4) cancer is not only infectious, but autoinfectious and in operations for the removal of cancerous growth, the possibility of infection should be constantly borne in mind. Besides a very interesting address of the retiring President, Dr. John Harris Jones, on "Some Stray Thoughts In and Out of Medicine," there are further important essays and contributions on pneumonia, empyema, leucemia, Parkinson's disease (paralysis agitans), serum test for typhoid fever, mastoid disease, and general medical topics.

Transactions of the American Ophthalmological Society. Thirty-fifth annual meeting. New London, Conn., July, 1899. Hartford: Published by the Society, 1899.

Although nothing startlingly new was presented, the meeting of 1899 was quite successful, 68 members being in attendance and 21 papers being read. The report is a profusely illustrated volume of 125 pages. The papers which excited most discussion were one by Johnson of Paterson, on the extraction of iron particles from the eye by means of the electro-magnet, and one by Williams of Boston, on more uniform tests of acuteness of vision, color sense, and hearing. Thompson of Philadelphia, and Dennett of New York were appointed a committee to report at the meeting of 1901 on the matter of standards and the best methods of making examinations of sight and hearing with particular reference to the marine and railway services.

Operative Surgery. By Joseph D. Bryant, M.D., Professor of the Principles and Practise of Surgery, Operative and Clinical Surgery, in the University and Bellevue Hospital Medical College; Visiting Surgeon to Bellevue and St. Vincent's Hospitals; Consulting Surgeon to the Hospital for the Ruptured and Crippled, Woman's Hospital, and Manhattan State Hospital for the Insane; Fellow of the American Surgical Association; former President of the New York Academy of Medicine; President of the New York State Medical Association, etc. Vol. I., with 749 illustrations. New York: D. Appleton and Company, 1899.

The fact that the third edition of this well-know treatise more than doubles its size, neces-

sitating its division into two volumes each as large as the original one, is indicative not only of the growth of an individual work, but is also significant in that it shows in a striking manner the advances recent years have seen in the development of the purely technical side of surgery. While the work of the pathologist and bacteriologist has been illuminating many of the more obscure corners of the science and exposing to the day-light of definite knowledge what formerly was accessible only to groping empiricism, the operator himself has not been less industrious than his aides and each advance in the understanding of etiology and morbid anatomy has been quickly supplemented by some improved diagnostic or operative measure.

In no other section, perhaps, is this more evident than in the field of brain surgery. For example, while in the first edition of this manual fifteen pages were sufficient to cover the entire matter of the surgery of the nervous system, in the present one nearly one hundred are given to the same subject. In a similar way the chapter on plastic surgery has been almost doubled and, in fact, the book is practically an entirely new one based simply on the skeleton of the old. The illustrations are unusually numerous and well selected; a novel and interesting feature is the grouping for each of the more important operations in a single photograph of all the instruments needed in performing it.

This volume considers General Principles, Anesthetics, Antiseptics, Control of Hemorrhage, Treatment of Operation Wounds, Ligature of Arteries, Operations on Veins, Capillaries, Nervous System, Tendons, Ligaments, Fascia, Muscles, Bursæ, and Bones, Amputations, Deformities and Plastic Surgery, and the pleasure it inspires causes one to look for the appearance of the second with much interest.

The Principles and Practice of Modern Surgery. For the use of Students and Practitioners of Medicine and Surgery. By John B. Roberts, M.D., Professor of Anatomy and Surgery in the Philadelphia Polyclinic; Mütter Lecturer on Surgical Pathology of the College of Physicians of Philadelphia. New (2d) and revised edition. Octavo, 838 pages, with 474 engravings and 8 plates in colors and monochrome. Philadelphia and New York: Lea Brothers & Co., 1899. (Price, $4.25.)

The purpose of the author of this work is to give to the profession in a condensed form the accepted doctrines and approved procedures of modern surgery. About one-fifth of the volume is devoted to surgical pathology, asepsis and surgical technic. In the second part the surgical diseases and injuries of the various portions of the body are systematically considered, usually under the three headings "pathology," "symptoms," "treatment." In every chapter it is evident that the writer has had constantly in mind a resolve to make this volume an every-day help to the surgeon, for he has given special attention to "treatment," and his directions are clear, concise, and easily understood.

The subjects treated make up the whole of general surgical practice, and the student who masters this book will have an up-to-date knowledge of surgery. The weak point of a revised book usually is that so much of the old remains, even although obsolete. Dr. Roberts has pruned with a free hand, and as a result he has saved himself from this criticism. The articles on Appendicitis, Diseases and Injuries of the Joints, Diseases and Injuries of the Genito-Urinary Organs, Dislocations, Excisions and Amputations, have been entirely rewritten.

The book is profusely illustrated, as the author has not hesitated to draw upon the latest surgical works of America and Europe for their best drawings, to which he has added many new ones of his own, including several radiographs.

The Trained Nurses' Directory. Composed of Names Carefully Selected by Prominent Physicians and Surgeons of New York and Vicinity from Their Private Lists. Compiled and Edited by M. Louise Longeway, Graduate of the New York Training School, Bellevue Hospital. Sixth Edition. 1899.

This handy memorandum book serves a number of useful purposes. It contains a classified list of graduates of the various training schools in and about New York, with lists of graduate trained nurses practising in Albany, Pittsfield, Hartford, New Haven. The addresses are given where the nurse may be found and if special nursing is done this in indicated. Lists of masseurs, medical stenographers and type-writers, street lists of New York and Brooklyn, obstetrical tables, office nurses, registers and nurses' homes and the training schools of New York and Brooklyn are presented in small compass. The work should find a useful place in the world of reference books.

Refraction and How to Refract. Including Sections on Optics, Retinoscopy, the Fitting of Spectacles and Eye-Glasses, etc. By James Thorington, A.M., M.D., Adjunct Professor of Ophthalmology in the Philadelphia Polyclinic and College for Graduates in Medicine; Assistant Surgeon at Wills' Eye Hospital, etc. Two Hundred Illustrations, Thirteen of which are colored. Octavo. 301 pp. P. Blakiston's Son & Co., Philadelphia, Pa.

This book is the result of the author's lectures on Refraction at the Philadelphia Polyclinic, and is written (the preface states) "for beginners in ophthalmology, especially for those with a limited knowledge of mathematics." It is an attractive volume, numerously illustrated.

It begins with a chapter (about 50 pages, with many illustrations) devoted to a clear and elementary discussion of optics, which is followed by another on the standard eye, accommodation, convergence, and the angle gamma and alpha; then come chapters on the ophthalmoscope, the

various refractive errors, retinoscopy, muscles, cycloplegias, "How to Refract," and applied refraction.

There is much useful information contained in the book, which is quite practical. It will be found of great assistance to those who are taking courses on refraction at our clinics, or who desire to acquaint themselves with the various methods of examination in this important department of ophthalmology.

A Text-Book of the Practice of Medicine. By James M. Anders, M.D., Ph.D., LL.D. Third Edition. Revised. Philadelphia: W. B. Saunders, 1899.

The popularity of this work among students and practitioners is evinced by the fact that three editions have appeared within two years. The second edition, issued less than a year ago, did not receive any notable revision. This, the third edition, however, has been quite extensively revised, especially in the section relating to Infectious Diseases. The following subjects not found in the previous editions have here found a place, to-wit: Glandular Fever, Ether-Pneumonia, Splenic Anemia, Neuralgia Paræsthetica, and Periodic Paralysis. The subjects of the Plague, Malta Fever, the Diseases of the Thymus Gland, the Cirrhosis of the Liver, and Progressive Muscular Atrophy have been practically rewritten. The introductory chapter on the Diseases of the Nervous System, dealing with localization and methods of investigation, is also new. Six new illustrations have been added. There can be no doubt that the work has been improved by these additions and alterations. The revisions have brought the subjects up to date.

The popularity of the book is doubtless due to the facts that the subjects are adequately described, clearly and succinctly presented, and offer to the student the facts of disease in an accessible and ready manner.

The Rise and Development of the Liquefaction of Gases. By Willett L. Hardin, Ph.D. New York: The Macmillan Co., 1899.

The volume before us treats in a most exhaustive manner of the history of the development of this branch of science, both as regards the theory and the methods employed in the liquefaction of gases. Both the practising physician, as well as the histologist and other research workers, are constantly using compressed or liquefied gases, such as oxygen, nitrous oxide, carbonic acid (for freezing fresh material to be cut by the microtome), and other gases, and it may be of interest to them to consult this work in order to inform themselves upon the processes of their manufacture. The recent methods adopted by Professor Dewar for the liquefaction of oxygen, air, nitrogen, etc., are also most ably discussed.

The last chapter deals mostly with the discussion of the physiological action and effect of low temperatures, the work of Cohn, Melsens and others on the action of low temperatures on bacteria and ferments being dwelt upon, the uselessness of low temperatures for sterilization being especially pointed out. The effect of low temperatures upon rabbits and frogs is also cited, and the investigations of Pictet and Dewar are briefly sketched. The book is well arranged and furnished with a most comprehensive index.

General and Local Anesthesia.—By Aime Paul Heineck, M.D., Clinical Instructor in Genito-Urinary Diseases, College of Physicians and Surgeons, Chicago; Clinical Instructor in Gynecology, Chicago Clinical School; Clinical Instructor in Surgery, Northwestern University Woman's Medical College. C. P. Englehard & Co., Chicago, 1900.

This monograph consists of 125 pages, devoted about equally to general and local anesthesia. It is arranged in two chapters, and comprises subdivisions or headings, as, the general use of chloroform and ether only; in obstetrics, for diagnostic, surgical and therapeutic uses; the selection of the anesthesia; posture and preparation of patient; rules for the administration of chloroform and ether, and precautions before and after: treatment in cases of accidents; methods of applying local anesthetics; the use of cocaine in the nose and throat; in genito-urinary surgery; precautions in cocaine anesthesia; and infiltration anesthesia and its technic.

The book abounds in many practical hints. The subject of anesthesia by nitrous oxide, however, either alone, or with oxygen, or to precede ether, is entirely omitted. The use of this important anesthetic is too important to be passed with simple mention. The chapter on local anesthesia is excellent, practical, and complete.

THERAPEUTIC HINTS.

Oil for Pyloric Stenosis.—Cohnheim reported a case seen in Boaz's clinic, in Berlin, of dilatation of the stomach apparently due to stenosis of the pylorus following traumatism (contusion of the abdomen, probably causing rupture of the mucous membrane, an ulcer, or hematoma of the gastric wall) in which the patient was completely relieved by taking linseed oil. He suffered from sharp gastric pain and vomiting, and presented all the symptoms of dilatation; lavage had done but little good. On the advice of a friend he began to take a wineglassful of oil morning and evening, after eating. He improved uninterruptedly, the vomiting ceased, and after five weeks of this treatment he was completely cured, and able to dispense with the oil except after a specially heavy meal. Cohnheim assumes that the oil facilitates the passage of the food into the duodenum by lubricating the mucous surfaces, and also lessens the irritation of the pylorus, to which its spasmodic contraction is due. He now advises trying similar treatment before resorting to operation in such cases.

VOL. LXXVI. NEW YORK, SATURDAY, MARCH 24, 1900. NO. 12.

ORIGINAL ARTICLES.

SUPRARENAL THERAPY.

BY W. H. BATES, M.D.,
OF NEW YORK.

WHEN we say, as I did in my first paper, that the aqueous extract of the suprarenal capsule is a powerful astringent, or when we say as I shall this evening that it is an ideal heart tonic, we fail to convey its true action. If we seek for words adequate to express in the scientific language of the day the unique action of this drug, the difficulty is to confine it within the lines of division placed by therapeutists and we long to drop the attempt, and exclaim with the patient, "Marvelous!" When we investigate either the physiological action or the therapeutic application of the active principle, we find that rules which have been considered immutable and principles fundamental are set aside when their action would be undesirable. For example, we expect a great dilatation of the blood-vessels to follow a powerful contraction. Of 2000 cases noted in which the suprarenal produced this contraction, the expected dilatation did not follow in one case, and, furthermore, it is a rule that when a minute dose of a drug causes an immediate and powerful effect, that drug is a poison. One two-hundredth of a grain of the extract locally applied will in a fraction of a minute replace the redness of certain inflamed eyes with a condition whiter than normal, and the suprarenal extract is not a poison. No untoward effect has ever followed the local or internal administration of the untainted gland. Two pounds of the fresh suprarenal capsule in the form of an aqueous extract have been swallowed without any apparent ill effects.

The extract when instilled into the eye is non-irritating. Its effect is temporary. A tolerance is not established by its daily use for months. It is not cumulative like digitalis. A suprarenal "habit" is not induced. The extract has no direct effect on the nervous system. The pupil is neither dilated nor contracted by it and the accommodation is not paralyzed. It is not an anesthetic.

When the extract is applied continuously to the healthy skin the parts are whitened after some time, usually in half an hour. If the epithelium be removed the extract whitens the skin in less than one minute. This effect is temporary. When the extract is administered hypodermatically the skin is blanched a dead white immediately and may be incised without primary hemorrhage. The suprarenal is an astringent of other tissues in addition to mucous membranes and the skin. The normal blood supply of the peritoneum, muscle tissue, brain and connective tissue, is lessened temporarily to a marked degree by the local use of the extract. All inflamed tissues are benefited. Granulation tissue is whitened and contracted. Velich lessened the blood supply of sarcoma in rats by the local use of the suprarenal.

Of great importance is the fact that the effects obtained by the local use of the extract can be obtained, although to a less degree, by the internal administration of this remedy. I have seen congestion of the eye, ear, nose, larynx and thyroid gland become decidedly less three minutes after the patient swallowed five grains of the dried gland. Congestion of the lungs, heart, liver, kidneys, bowels, brain, and cord, have been also promptly relieved.

Suprarenal Preparations.—The pulverized dried gland keeps indefinitely and can be readily obtained. For local use in the eye a *fresh* aqueous extract should be prepared by mixing one part of the dried gland with ten parts of water. The mixture is allowed to stand five minutes and is then filtered. The filtrate contains about one per cent. of the active principle. This solution may be sterilized by heat. Chemicals do not preserve the extract in solution without impairing its astringent property in the eye. The solution spoils in a few hours and has then caused infection of the eye and nose.

An *emulsion* of the powder in water has been used in the nose and urethra with benefit. It also must be freshly prepared.

Chemical Properties.—The suprarenal extract is very soluble in water, insoluble in strong alcohol, ether and chloroform. It is a strong reducing agent. The aqueous solution gives with ferric chloride an emerald-green color, and with solution of iodine a beautiful rose-carmine tint. An alkaloid has been isolated by Abel and Crawford, which they have called "epinephrin." It has the properties of the aqueous extract when used in the eye, ear and nose, and has the great advantage over the aqueous extract that it does not spoil readily when in solution.

Physiological Properties.—Oliver and Schäfer[1] find that the extract increases the tone of all muscular tissue. The intravenous injection of minute doses raises the blood-pressure enormously while larger doses of digitalis and ergot produced no appreciable effect. Cleghorn[2] experimented with the isolated dog's heart and found that the strength of the contractions were doubled by the suprarenal, which he believed

[1] Read in part before the New York County Medical Society, February 26, 1900.

acted directly upon the heart-muscle. Dreyer[3] found the active principle in the suprarenal vein, and believed it to be a true internal secretion.

When the suprarenal is administered hypodermically, or by the mouth the effects are different from those obtained by the intravenous method when employed on animals. The blood-pressure is not appreciably raised in the normal individual. When the heart is weak it becomes stronger. I shall refer to this later.

Nose and Throat.—The astringent and hemostatic properties of the suprarenal in diseases of the eye suggest its use in diseases of other mucous membranes. The mucous membrane of the nose is whitened in less than one minute by the local application of the aqueous solution of the extract. This result always occurs. It facilitates examination of the nasal chambers by reducing temporarily swelling of the mucous membrane covering the turbinated bodies and the septum.

It is an adjuvant to cocaine in securing anesthesia. Better results are obtained after the use of the cautery when the parts are first blanched and shrunk with the extract. All forms of tonsillitis are temporarily relieved by the local use of the extract. Congestion of the mucous membrane of the larynx is temporarily relieved also. I do not believe the extract cures any disease of the nose or throat. Its great value is in changing a severe inflammation into a very mild one, so that the usual remedies are better able to cure.

The extract relieves congestion of the nose and throat by the internal administration. In acute rhinitis the swelling of the turbinated bodies has subsided in three minutes after the ingestion of five grains of the dried gland. The pain of tubercular laryngitis has been temporarily relieved in the same manner, the extract lessening congestion of the larynx.

Hay-Fever.—The suprarenal has been used with great benefit in many cases of hay-fever. After the local use of the fresh aqueous solution, the nose opens, the discharge stops and the patient feels comfortable in five minutes. The effect is temporary and the remedy has to be applied frequently, in some cases every two hours. The disease then becomes less severe and the extract is required less frequently. The internal administration is also followed by relief. Cohen, Douglass and others have reported marvelous cures with the suprarenal. See also an excellent paper by H. L. Swain.[4]

Eye Diseases.—My original observations on the therapeutic properties of the suprarenal extract were made in the treatment of diseases of the eye. I have found it of great value in lessening the congestion of conjunctivitis, keratitis, iritis and scleritis. Although the suprarenal is not an antiseptic it has been of great service in purulent inflammations of the conjunctiva and cornea by relieving congestion. It gives tone to the blood-vessels and strength to the heart, thus increasing the resistance of the tissues to the invasion of germs. I believe that I have saved the sight in some cases of purulent keratitis with the extract which without it would have been lost. All my clinical observations of the action of the suprarenal have been of diseases of the eye, ear, nose and throat, my work being entirely in this field. The eye furnishes excellent opportunity for the study of the results and limitations of the action of any drug used locally. In addition to its action in catarrhal and purulent inflammations, the suprarenal is valuable in hastening the absorption of connective tissue which follows these inflammations. I have studied the long-continued use of the extract, in addition to other astringents, in the treatment of opacities of the cornea. Examining with the glass the minute blood-vessels usually found near the opacity are seen to become smaller after the extract has been instilled; coincidentally, the vision is improved. The long-continued contraction of these blood-vessels is followed by absorption of the connective tissue. By the use of this treatment in a recent case of corneal opacity the vison was improved from $^1/_{10}$ to the normal in three months and the corneal opacity disappeared. In those cases of lachrymal stricture and abscess of the sac, in which an operation is required to obtain relief, I have usually been able to cure the disease by the use of the suprarenal supplemented by other local treatment without the use of the knife. I do not believe any words of mine can adequately describe the effect of the extract in such cases. One patient had an acute abscess of the sac with so much swelling that the eyelids were closed. The pain was severe. I syringed the extract frequently into the punctum until, the congestion being relieved, I could press out the pus. In five minutes the nasal duct was open and the abscess drained. The redness, swelling and pain disappeared after the frequent use of the extract for twenty minutes. The patient was cured. In other cases immediate relief was obtained, but the patients were not cured until after some time. Strictures of the nasal duct caused by congestion were opened by the powerful astringent property of the extract and were cured without operation.

After operations on the nasal duct the extract is of great service in lessening congestion during healing. In operations for the cure of lachrymal stricture the extract is of great benefit in securing a painless operation with cocaine, and in lessening hemorrhage. I have in some cases been able to operate bloodlessly. The great value of the extract in lachrymal stricture suggested its use in the treatment of strictures in other parts of the body. I have been told that some urethral strictures were benefited by the astringent property of the extract, and the hemorrhage which usually occurs after internal urethrotomy has been materially lessened by its local use.

The internal administration of the suprarenal lessens congestion in diseases of the eye, although the results are not so decided as when the extract is used locally. In one case of chronic glaucoma the tension was lowered and the vision improved.

The following case of optic neuritis was benefited by the internal administration of the suprarenal:

A woman under treatment for syphilis developed at the same time optic neuritis with a loss of vision. The suprarenal powder was prescribed, gr. iii, t.i.d., which was followed by a marked improvement in her vision. Later the suprarenal was stopped and the vision became worse. When the suprarenal was resumed, the vision improved at once and is now normal. She is still taking the mixed treatment.

Ear Diseases.—The extract when applied to the orifice of the Eustachian tube in the vault of the pharynx lessens the congestion of the drum membrane and of the middle ear in acute and chronic catarrhal otitis media. The tinnitus is lessened and the hearing improved. This effect, however, is temporary. I have been able to improve the hearing in some cases of sclerosis with the extract which were not benefited by politzeration. To obtain permanent benefit it was necessary to employ other treatment with the suprarenal. During the past winter I have found the internal administration beneficial and now prescribe it in all my ear cases which suffer from congestion.

Hemostatic Properties.—The suprarenal is the best hemostatic known. It acts by contracting the small arteries and has no chemical or other effect on the blood itself. I have controlled severe nasal hemorrhage in a "bleeder" by syringing the nose freely with an emulsion of the powder after peroxide of hydrogen, sulphate of iron, gelatin, antipyrine, and cotton plugs had failed. The hemorrhage is stopped promptly, usually in less than three minutes, when the parts can be reached. Since the suprarenal is non-irritating and does not form clots, as does iron, it is not an objectionable hemostatic. Bloodless operations are performed on the eye and nose when the parts can be blanched white. If large veins are seen and opened, hemorrhage naturally follows. This can be controlled by the extract. Secondary hemorrhage is lessened by the extract. The extract does not prevent secondary hemorrhage after lachrymal operations. One may expect secondary hemorrhage after nasal operations when the bone is laid bare. The hemostatic effect of the suprarenal is temporary, and it may be necessary to use it every two hours for a number of times before the hemorrhage finally ceases. I am well pleased with the hemostatic property of the freshly-prepared suprarenal.

Dr. Moschcowitz controlled urethral hemorrhage in a case of hemophilia and there was not any secondary hemorrhage. Otis has used the extract with success in controlling hemorrhage from the bladder. Dr. T. P. Berens has used the extract with cocaine hypodermatically and performed a bloodless plastic operation. Dr. J. A. Mullen used the extract hypodermatically on a patient under ether and prevented hemorrhage during a plastic eyelid operation. Dr. J. A. Moore has also used the aqueous solution hypodermatically to lessen hemorrhage after cutting the meatus. I wish to caution all operators to use a freshly prepared aqueous solution because the hypodermatic use of the spoiled extract, while it blanched the skin a dead white, caused in one case a rise of temperature to 104° F., with other disagreeable symptoms. The aqueous extract has spoiled in one hour.

Addison's Disease.—The suprarenal has been used with benefit in this disease. The literature on this subject is very extensive

Asthma.—S. S. Cohen has used the suprarenal with benefit in some forms of asthma.

Exophthalmic Goiter.—I believe that S. S. Cohen[5] was the first to publish the results of treatment of exophthalmic goiter with the suprarenal capsule. G. W. Crary[6] also has observed improvement in the action of the heart, the tremor, the general muscular strength, and a disappearance of the goiter. Dr. E. Danziger furnished me with the notes of the following case of exophthalmic goiter, in which the suprarenal gave immediate relief: Girl, aged fourteen years, for six months had suffered from discomfort around her throat, palpitation of the heart, throbbing of the carotids and abdominal aorta, with shortness of breath after slight exertion. The thyroid gland was enlarged; the circumference of the neck was twelve inches; the heart sounds were normal; the pulse beats were 120 in a minute. The dried suprarenal was prescribed, gr. ij, t.i.d. When the patient was seen two days later the pulse was 88 per minute, the throbbing of the large arteries was relieved, and the shortness of breath had disappeared. The gland was less swollen and the circumference of the neck had diminished one inch, being now eleven inches. When after two weeks the suprarenal was stopped a relapse followed. When the suprarenal was resumed, the patient again improved. Dr. Danziger had two cases of parenchymatous or cystic enlargement of the thyroid, without general systemic disturbance, in which the suprarenal produced no immediate, apparent benefit. The following case of exophthalmic goiter was benefited by the suprarenal, the general circulation being improved:

A woman with exophthalmic goiter had a jerky pulse of high tension with a labored heart. After five grains of suprarenal were administered the heart's action improved, the throbbing of the arteries diminished, and the pulse became softer and more like normal. The frequency of the pulse was 90 immediately before the administration of the suprarenal; one hour afterward it had not changed. The swollen thyroid gland became softer and the circumference of the neck became one-half inch less in ten minutes.

Heart-Disease.—When the suprarenal extract is instilled into the eye, frequently, enough is absorbed to affect the general circulation as well. I have observed a weak, intermittent pulse of organic heart-disease become strong and regular with relief of the subjective symptoms after the instillation of a one-per-cent. solution of the ex-

tract every two hours in the eye. This case was seen six years ago. Since then the extract has been used in the eye in other cases of heart-disease with benefit. At first it was feared that a remedy so powerful for good would be equally powerful for harm, and that in some cases of heart-disease the use of the extract in the eye would injure the heart. I have looked for the cases in which the extract was contraindicated, but have not found them. It seemed so important to understand the action of the suprarenal on the heart that I made clinical observations of the pulse in all my eye cases with heart-disease in whom the remedy was used. Recently I made some sphygmographic tracings of the pulse before and five minutes after the administration of five grains of the pulverized gland by mouth in twelve cases of organic heart-disease. My conclusions agree with those of Oliver and Schäfer, Valentine, Cleghorn, Boruttan, Greenbaum, Cunningham, Kinnicutt, and others, and are as follows: (1) The internal administration of the suprarenal does not affect the normal heart or normal blood-pressure, or the normal pulse in organic heart-disease. (2) An intermittent pulse becomes regular. (3) A weak pulse becomes stronger. (4) A rapid, weak pulse becomes less rapid and stronger. (5) When anemia or hyperemia of the vessels of the face and of the extremities is present, the administration of the suprarenal is followed by a return to the normal because the increased strength of the heart-beat equalizes the circulation and, consequently, the distribution of the blood to all parts of the body. (6) The action of the suprarenal is temporary. (7) The extract of the suprarenal capsule is the most powerful known stimulant of the heart.

The effect of the suprarenal on the normal blood-pressure by the internal administration has been studied by Grünbaum[7]. He used Oliver's sphygmodynamometer and in no case was there an appreciable rise of blood-pressure even after the ingestion of thirty grains of the dried gland. Kinnicutt[8] has used the adrenals in a few cases of heart-failure, with apparent benefit. Oliver[9] has seen benefit where the vasomotor tone is lowered, as in asthenia and anemia, from the internal administration of the suprarenal. In cyclic albuminuria he also states that he has obtained good results with this drug. (See also "Pulse Gauging," by G. Oliver.) E. O. Hultgren and Oskar A. Anderson[10] found, like Gottlieb, that when the heart's activity was reduced by chloral, an injection of the extract greatly strengthened it. The following case was temporarily relieved after digitalis and some other treatment had failed:

A man, aged sixty years, had general arterial sclerosis with a double aortic and double mitral murmur. The patient was in bed, too weak to rise. I was unable to feel his pulse at the wrist. His hands were cold. He was given five grains of the powdered suprarenal. In ten minutes his hands were warm and the pulse was felt quite strong at the wrist.

CONCLUSIONS.

1. The aqueous extract of the suprarenal capsule when used locally is the most powerful astringent and hemostatic known.

2. By reason of its action on the heart, congestion of the mucous membrane and other tissues of the eye are relieved to a less degree by the internal administration.

3. Congestion of other organs in addition to the eye are relieved by the local and internal use of the extract.

4. The extract is useful in all forms of inflammation and in inflammations in all parts of the body.

5. The suprarenal is the strongest known stimulant of the heart.

Finally, we may say that the reason why so little disturbance has followed the use of this powerful substance for six years by so many observers is that we are using a material which is necessary to the normal functions of the body, and I wish to repeat that within the limits of its sphere of activity no other substance can take its place.

SOME DIRECTIONS AS TO THE CARE OF THE HAIR.[1]

By GEORGE THOMAS JACKSON, M.D.,
OF NEW YORK;
INSTRUCTOR IN DERMATOLOGY IN THE MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY, ETC.

THERE are certain matters in regard to the care of the hair that have not been taught to some physicians in their student days, and about which they are still somewhat at sea because they have found no mention of them in their books. About these they seek advice. Perhaps such matters may seem trivial to some of you, but they do not seem trivial to some of your patients. Therefore, they seem to me to be of sufficient importance to warrant my bringing them briefly to your notice.

Management of the Hair During and After Fevers.—It is well known that the hair falls after fevers and parturition, as well as after other exhausting drains on the general nutrition of the body. The laity know this, and in such cases are constantly asking if we cannot do something to prevent the fall of the hair. After the patient is convalescent, his or her, especially *her*, friends are eager to have the head shaved and cross-shaved, and cite cases of those who have had this

[1] Read before the Medical Society of the State of New York, Albany, January 30, 1900.

done and now have such magnificent hair! How shall we answer these questions? We can answer the first by saying that nothing can be done during the illness to prevent the fall of the hair. The hair falls not because of the dryness of the scalp in consequence of the fever, but because its nutrition has been interfered with by the illness. This we know because the hair will fall in some non-febrile disease. All we can do is to keep the hair and scalp in order by gentle brushing and combing, and by rubbing into the scalp once or twice a week the least little bit of vaseline or oil. To the demand for permission to cut the hair short or to shave the scalp, we should give emphatic denial. It is a serious business to shave the scalp of a woman and chiefly benefits the barber, who, by the way, is the one most urgent to have it done. It dooms the woman to months of wearing a wig, and to many subsequent months of remarks from the thoughtless and cruel because she, perforce, is a member of the short-haired sisterhood. As it is impossible to say how much of the hair will fall, and as it is rare for enough to fall to render "doing up" impracticable, there seems to be no reason to subject the woman to the positive annoyances of the shaving with advantages so exceedingly doubtful.

Well, shall we do nothing but simply fold our hands and let Dame Nature look after the hair? It would be much wiser to do this than to do some things that are done; but we can do more. We should allay the fears of the patient and her friends by assuring them that although the hair may fall for a few weeks, it will grow in as well as before the fever if they will obey directions. They must be directed to brush and comb the hair every day. At this they will throw up their hands in horror and exclaim: "Why, doctor, I am afraid to brush my hair as so much comes out." We can tell them that that need not disturb them in the least, as only the already damaged hair can be pulled out in that way and that the sooner they are out the better. Once or twice a week a little of a pomade composed of a dram of precipitated sulphur in an ounce of a good, soft cold-cream should be gently worked into the scalp. Every two or three weeks the hair and scalp should be washed, and a little of the pomade applied as soon as the hair is dried. As the patient regains her strength, if she follows this method of caring for the hair, she will be rewarded by having as fine a growth of hair as she had before, if not finer. Of course, the older a woman is the less the probability for this much-to-be-desired outcome.

How Often Shall the Scalp Be Washed?—This is another question often asked. We can answer that once in two to four weeks is sufficient, so far as the hair is concerned. In fact, it does not seem to make much difference to the hair whether it is washed or not. It is more cleanly to wash the hair and that is the greatest reason in favor of doing it. It is bad to wash the hair too often, and daily sousing of the hair, as is the too common practice, is pernicious.

Soaps.— We will be asked what soap is best to use in washing the scalp, and many women who make their living by caring for the hair have some mysterious soap which they use, vaunt, and try to sell to their customers, but the composition of which they will not reveal. As a matter of fact, except in a very few conditions of the scalp, it makes little difference what sort of soap is used, provided it is made by a good manufacturer. The most convenient soap is one that is liquid, such as the tincture of green soap. Whatever soap is used must be thoroughly washed out with plenty of water. After washing the scalp a little pomade or oil must be rubbed into the scalp to take the place of the natural oil that has been removed by washing.

Use of Pomades.—The men of my father's generation habitually used pomades on the scalp. To protect the chair coverings from the grease on their heads tidies came into vogue. Then the pendulum swung the other way, and now pomades of all kinds are tabooed. That there has been a great increase in baldness among the young men of the present generation is a general impression, although I know of no statistics to support or refute it. Some fifteen years ago, when I first became interested in the study of diseases of the hair, I accepted the teaching of the time that pomades did no good, and, becoming rancid, did positive harm. With enlarging experience I am becoming more and more convinced that I was wrong and that one reason why the hair is lost so early now-a-days is because the sons have forgotten the teachings and practice of their fathers in regard to the use of pomades. They neither use pomades nor seek to stimulate the natural oily supply to the hair by systematic brushing. Instead they daily wet their heads with water to enable them to arrange their hair. By not using pomades and by wetting the hair instead of brushing it, their hair becomes more and more dry, dandruff increases, and their hair falls. I believe that if boys were trained to brush their hair thoroughly every night and morning, and had a little pomade that will not turn rancid, such as contains sulphur or salicylic acid, for instance, rubbed into their scalps once a week or so, and avoided wetting their heads, baldness in the rising generation would not be so prevalent as it is in this.

Cutting the Hair.—We are sometimes asked how often the hair should be cut. It makes no difference how often it is cut. It is purely a matter of taste. No one would think of asking how often the nails should be cut, but cuts them as often as they become too long for comfort or taste. Cutting the hair will neither increase nor decrease the amount. It will stimulate the fine hairs to become coarser, but when they have reached their normal growth cutting will have little influence on them. It is always advisable to direct that the split ends of the long hair of women should be cut off above the cleft, as this will prevent the cleft from traveling up the hair. It is best not to have the hair of a girl cut after she

is ten or twelve years old, because if left to itself and given adequate care it will grow more silky than if it is cut.

Singeing.—Of all the foolish fashions in regard to the care of the hair that of singeing is the most ludicrous. It is founded on an antiquated idea, and is a revival of an antiquated fashion. Away back in the dark ages it was thought that when the hair was cut it bled from the cut ends, or, at least, lost some fluid nutritive substance. Therefore, it was argued, we should singe the ends to prevent this loss, just as it once was the practice to sear wounds to stop hemorrhage. As the hairs are not hollow tubes like arterioles and neither bleed, exude, nor ooze in any way when cut, the operation has no foundation in fact, nor does it do any good. I have seen scores of barbers' customers who have gone about like singed cats for months and without benefit.

NEUROLOGICAL OBSERVATIONS IN THE HAWAIIAN ISLANDS.[1]

By DANIEL R. BROWER, M.D.,
of Chicago, Ill.

It was my privilege during this summer to spend six weeks in these islands, and I present herewith a synopsis of the observations made. The Hawaiian Islands are remarkable for the uniformity of their climate. At sea level the average summer temperature is about 85° F., and the winter temperature about 80° F., and the difference between night and day is not more than ten or fifteen degrees. They have a great variety of climates so far as high and low levels are concerned, and dryness and moisture. The islands are very small in size, comparatively, and have elevations upon them that range from 4000 to 14,000 feet. Trade winds are almost constantly blowing in the same direction, that is, from the northeast, and these high elevations precipitate the moisture of one side, making the rainfall on the windward side very considerable, and on the leeward side almost nothing. Then, by ascending the mountain-sides one may secure a much lower temperature, on Mount Loa, even to the freezing point. We spent a week on the leper island, at an elevation of 1500 feet, and found the nights cool enough for blankets, so that it is possible to secure on the islands almost any desired climatic condition. The general effect of the climate on the average Anglo-Saxon at sea level is one of depression, and as a consequence neurasthenia is not uncommon, especially among the women, and they feel it necessary periodically to leave the islands and return to the Coast for the purpose of recuperation. Several women informed me that three years was the longest time they could remain on the islands at sea level without suffering profound symptoms of neurasthenia, and as the most desirable places on the islands are at sea level, it will not be a good place to send our neurasthenic patients. The remarkable uniformity of temperature makes it a desirable place for the spinal scleroses generally. These diseases do not prevail there to anything like the extent that they do in this country. The climate is also desirable for cases of interstitial nephritis. I had an opportunity of observing the relations of the islands to insanity, and obtained from Dr. Humphries, who was in charge of the Hospital for the Insane, at Honolulu, much information. This hospital is a very creditable one. The buildings are well constructed and commodious, and the climate makes it possible to use an out-of-door treatment quite universally. During my visit every patient was out-of-doors. The grounds are abundantly shaded with fine specimens of the umbrella tree and the cottages are provided with large verandas. The types of insanity among the natives are generally mild. It is not usual to have the violent manifestations of mania. The violent cases that were at the hospital at the time of my visit were either foreigners, or else they were mixed in their nationality. The proportion of insane to the population as near as could be ascertained is about one to a thousand. Notwithstanding the great prevalence of syphilis among the natives, Dr. Humphries informed me that they have never had a case of general paresis in the institution from among the native population. I saw one paretic there, but he was an Anglo-Saxon. Paranoia is a form of insanity that has not been observed among the natives. There was one such case in the hospital at the time of my visit, but he was an Englishman. Suicides are practically unknown among the natives. There have been suicidal cases in the hospital, but they are usually Chinese or Japanese.

We had a very good opportunity of making observations on the subject of leprosy, and inasmuch as we now possess these islands, Cuba, Puerto Rico, and the Philippines, the question of leprosy is one of great importance to the profession. I have no doubt our armies returning from our new possessions will bring this disease with them. Leprosy was introduced in the islands in the year 1848 from China, and the authorities have been endeavoring by the most vigorous segregation of the lepers to stamp it out; they are making some headway in the work, but it is scarcely commensurate with the energy of their methods. There have been more than 6000 lepers consigned to the Island of Moloki since the work of segregation began, thirty-five years ago. There are now 1200 lepers in this settlement. It is an ideal place. They occupy a tongue of land at one end of the island, and separated from the balance by a precipice that is from three to five thousand feet high. We can from personal experience testify to the extreme difficulty of getting down this precipice to the colony and returning to the other part of the island. The lepers are taken care of here and provided with anything necessary for their comfort by the general public. There are some interesting things to be noted about the children. They have in Honolulu, near the receiving station for lepers, a home conducted by

[1] Read before the Chicago Neurological Society.

the Sisters for girls; they have in this home some thirty or forty girls who were born in the settlement of leprous parents, and when they were found to be clean at birth or non-leprous, they were taken from the settlement and brought to this home, and in the experience of the Sisters, who have been running this home for fifteen or more years, there has not been a case of leprosy developed there. The Board of Health feel that they are getting the disease under control, but it is not a very rapid process. In conversation with the members of this Board, we ascertained that the proportion of the anesthetic or nervous form of leprosy on the islands does not exceed 25 per cent. The tubercular forms constitute fully 50 per cent. of the cases, and the balance are of the mixed type. Suspected cases of leprosy are sent to a receiving station near Honolulu, and there once a month the physicians of the Board of Health meet for their diagnosis. It was my privilege to be present at one of these investigations, which began at noon and ended at six o'clock, during which time some forty lepers, the accumulation of the preceding month, were examined. Out of this number there were only four neurotic cases, one of which was put on the suspect list, and was not sent to the settlement, but was required to report to the health officer at stated intervals until the case was fully disposed of. Several of the cases were disposed of in a similar way, and some of them were postponed until the next Board meeting, a unanimous decision of the Board being necessary to send a case to the leper settlement. The physicians of this Board, who are experts, indeed, on this important subject, have abandoned the hereditary etiology, regarded it as contagious, and account for its rapid spread among the natives by their lowered resistance, a consequence of the great prevalence of syphilis and their socialistic tendencies. They live principally on two articles of diet, one called poi, and the other is fish. This poi is eaten by the natives out of a common vessel, and with their fingers; the ordinary native dips his first and second fingers into the poi-dish and carries the poi to his mouth, and then takes a bite of his fish, and has no fear of leprosy. They make a persistent effort to secrete the suspected cases from the health officers, so that many of the cases that were at this examination were cases of long standing; that is, from two to three years' duration, and these cases had doubtless widely scattered the bacillus before they had been brought before this examining board. The failure of efforts at early segregation is probably one reason why the work of stamping out the disease has not been more successful. It does not prevail to any great extent among Anglo-Saxons. During our visit to the settlement we found only six Anglo-Saxons there. The opinion prevails that the contagion occurs largely through the oral and nasal secretions. Active catarrhal symptoms were present in the great majority of the cases, and the propagation of the disease from the oral secretions is facilitated by their habits of eating and smoking each other's pipes. We had an opportunity of examining numerous cases of the anesthetic form. We were told that these cases usually begin with an erythematous eruption and with hyperesthesia, which later gives place to the anesthesia and later still to the motor symptoms. The ulnar and peroneal nerves are the usual seat of the attack. The invasion of the ulnar nerve by the neuritis develops the characteristic claw-hand of the leper. The diagnosis is made on the condition of the member and of the nerve; the diffused enlargement of the nerve, amounting in some cases to three times its normal size, an enlargement that is not uniform or symmetrical but nodular. The probability is that the bacillus begins its work in the sensory end organs in the skin; that it travels up the sensory nerves until it reaches a place where the nerves become mixed, sensory and motor, and when this progressive interstitial neuritis involves the motor and sensory filaments of the nerves, the muscular atrophy and the contractions become manifest. The difficulty in diagnosis is the differentiation of the leprosy from a neuritis that may have its origin in other causes. In the case of a young girl who was examined at this session of the Board and put upon the suspect list, there were very few erythematous patches, none of the white patches, slight enlargement of the nerve, but muscular atrophy and contractures. She will be kept under observation, reexamined in the course of a few months, and, of course, if found leprous, will be sent to the settlement.

We saw several cases of amputation of the toes and fingers from the progression of the atrophic processes, and these cases are difficult of differentiation from Reynaud's disease. Some of the cases presented a symptom complex that made them difficult to differentiate from syringomyelia. In doubtful cases the microscope is of great service in diagnosis, but it requires an expert to differentiate the bacillus of leprosy from the bacillus of tuberculosis.

The subject of incubation is important. In the case of a convict who was inoculated, the disease began to develop in about five years thereafter. In another case the period of inoculation fixed with some degree of accuracy was followed by positive manifestations of the disease in about the same number of years. The tuberculous cases run their course with rapidity. The anesthetic cases are long-lived. There are at the settlement several cases of about twenty years' duration.

As to treatment, nothing whatever has been found that can reasonably be called curative. Hot baths afford a great amount of relief and diminish, in some cases at least, the rate of progression. These baths have been medicated in a great variety of ways, but it is the impression of Dr. Oliver, who has been for many years the resident physician of the settlement, that it is the heat and not the medicament that produces the results.

Dr. Oliver's general plan of treatment is mildly alterative, tonic, and when necessary anodyne. He has seen excellent results from the very free

use of strychnine. Climate exercises a considerable controlling influence over the progression of the disease. Some of the lepers who have been taken to the settlement and given residence in the mountains of Japan have done so remarkably well that they have seemed almost to recover.

The great problem in connection with this disease is the prophylaxis. The efforts at segregation on the island have not been followed by as good results as its advocates had hoped for in the beginning, largely due, I think, to the fact that it is impossible in the very nature of things to enforce it early and thoroughly. There is no doubt that many of the cases of leprosy begin as nasal catarrh, and the man goes around spreading the disease broadcast for years before such positive evidence of the disease presents itself as to justify his segregation, and how to control this is a great problem. I think the health officers are doing everything in their power to make it a success, and the failure is due to the long period of incubation and the insidious onset of the disease.

In connection with the differentiation of progressive muscular atrophy, Reynaud's disease, Morvan's disease and syringomyelia, I think the recent observations of Zambico are very interesting. This physician considers that these several forms of nervous disease are simply modified forms of leprosy, the remnants of the leprosy that disappeared from Europe during the fifteenth and sixteenth centuries.

ALCOHOL AS A GENERAL STIMULANT AND HEART TONIC; ITS USE TO THE ANIMAL ECONOMY IN HEALTH AND DISEASE.[1]

By T. J. HILLIS, M.D.,
of New York.

The author of this paper will not follow in the footsteps of others who have preceded him, writing on the subject he has chosen to present to you to-day, that is, to give a long and labored description of the chemistry of alcohol and go into a wearisome and detailed account of its physical properties, as they are fixed and no doubt well known to all. In omitting this usual introduction a load is lifted off your shoulders, as it was not from mine when I had to sit time after time and with excruciating agony listen for what appeared an age to that which had better be read from a text-book, as most of it was only a clumsy copy.

The writer will not burden your minds with an array of citations from the various writers on the subject of which he addresses you to-day; he believes that little is gained by such quotations other than to weaken the force of his own argument and further complicate and muddle certain features of the question to be determined. The opinions and conclusions of any writer I might here refer to are known to all of you, then from me it would be only coming second-hand, and the time allotted me now is so brief that I cannot afford to deal in second-hand material, as Dr. Bristow once said, "Let the searcher after facts compare the notes of original writers and draw his own conclusions, then, while making his comparisons he will not be buried in a heap of references and enveloped in a fog of uncertainties, which, after all, lean on the investigations of a single man, but padded and quilted to suit the purpose of others who are trading on the brains of the original thinker."

For this reason nine-tenths of the medical literature of to-day is conspicuous by its dearth of ideas and absolutely worthless on this account, the men who write the books being, some of them, plagiarists and most of them copyists and compilers. In consequence of this state of affairs the market is glutted with so-called medical books, magazines and pamphlets that make our tables groan with a weight of stuff that should have reached the waste basket long before it was set up in type.

B writes a book, better he didn't. The central figure and the axis on which it rotates is the investigator A. Take away A, and B sinks into obscurity. There are, however, a few things about alcohol of which notice can with propriety be taken here, as they throw light on part of its physiological action, and are consequently of importance when we come to speak of alcohol in its relation to the human body in health and disease.

Alcohol is a generic term and is used to denote a number of substances resulting from the displacement of an atom of hydrogen from the saturated hydrocarbon compound CH_4 by an atomic equivalent of another elementary substance. Those alcohols are known as the marsh-gas series and are always found to be some multiple of the carbon radical CH_2 with the saturated hydrocarbon compound CH_4.

The oldest of these compounds, and the one best known, is the hydrated oxide of ethyl, which is alcohol. These alcohol substances differ widely in physical properties; some are gases, some fluids and others solids at ordinary temperature. Carbolic acid is an alcohol, so is glycerin, so are fats (cetyl alcohol).

The word alcohol is objectionable to the writer because he thinks it is misleading, as it might be supposed to be the beverage that we, or some of us, occasionally drink for health or companionship, but since it is in use by others to designate a particular product and to mean a definite thing, he, to avoid misunderstanding, will also adopt it. It is as consistent to say that the spring of your watch is pig iron as that the beverage that so few of you gentlemen drink is alcohol.

There is more alcohol in a cheap whiskey than in a dear one; just as there is more pig iron in a poor watch-spring than in a good one. Alcohol can be extracted from old hats or old shoes (but it would hardly pay). Anything possessing a saccharine or starchy substance will yield up some form of alcohol in presence of a ferment and un-

[1] Read at the 16th Annual Meeting of The New York State Medical Association, held October 24, 1899.

der favorable conditions. Now, it is as fair to say that we are eating old shoes as that we are drinking alcohol when some kind friend invites us to his social board to sip with him his Prince Maternish or his rare old St. Julian. The old shoes passed through a transformation to become alcohol, so did the alcohol suffer a change to reach the perfection of St. Julian.

The hydrocarbon in the old shoes was converted into alcohol by a process of oxidation; the process continued in the alcohol was a higher oxidation, which resulted in ethereal compounds, which now replace it in the product. Alcohol is said to be absolute when deprived of the water with which it is mixed; it loves this water so much that it is necessary to place decoys in its immediate vicinity to coax it away. (These decoys are called higher affinities.) It is then said to be absolute and anhydrous. The lighter the alcohol is, the more pure, and the higher it is prized in the arts and manufactures, but the more dangerous as a drink and the more useless as a popular beverage. For this reason it is not used at all, but put away with the water with which it is mixed by distillation for some time, the longer the better.

Several alcohols are found together in a single fermentation, and during the process of a distillation the one which evaporates or vaporizes first is the alcohol we recognize and adopt; it is known as ethyl alcohol. Now, another alcohol is heavy and does not evaporate so easily because it contains four times more carbon than the other; this is known as amyl alcohol. In order to have good whiskey it is absolutely necessary that this latter alcohol be mixed in a certain small proportion with the other, as it is so rich in carbon. When this carbon is burned out by slow combustion (and no sooner) the whiskey is fit for use; it takes from ten to twenty years to do this, and even after that the oxidizing process is still going on and new elements evolved by the metamorphosis of old ones, namely, ethereal compounds and gases so valuable a trait in wines and whiskies. They are now called old vintages. New whiskey is not fit for use because it contains raw hydrocarbons in the shape of oils and gases. One of these oils is amyl alcohol, and it is known as fusil oil. It is a powerful intoxicant and very poisonous, but the principal ingredient of the cheap whiskies to be found in grog-shops and dives. At present the manufacturers and distillers are trying very hard to neutralize the effect of the amyl alcohol in their new whiskies by various devices, such as adding glycerin, which, as we have said, is itself an alcohol, but away up in the series, to give smoothness and body, and olefiant gas, which is also an alcohol, to give flavor; but at best these are clumsy devices, and their efforts have met with poor success, as it is almost impossible to counterfeit synthetically an organic compound.

Leave the fusel oil in new whiskey and it is a poison; take it out and the whiskey loses its fire—its spirit, as it were. As the ethereal oils and gases formed by the substitution of alcohol radicals for hydrogen in the acetic and other oxid compounds of the hydrocarbon group are the life of old wines, so the fusel oil and other organic ingredients are the soul of new whiskey. The only way to remedy the evil is, don't sell new whiskey, as it is not fit for consumption, because it is not ripe, and to drink it is like eating green apples.

The good quality of whiskies and wines is developed by the presence of fusel oil and other impurities always to be found in fermented liquors made from cereal and vinous products. It is the oxidation of these substances which calls the alcohols into existence and favors the new combinations which are continually occurring during the slow fermenting process called ripening. As the alcohols themselves resulted from the presence of a ferment with saccharine substances in solution under the influence of heat, so the aldehydes and haloid ethers cannot be evolved save by the destruction of fusel oil.

The presence of amyl alcohol, then, is always essential for good whiskies, but in order to make fine whiskies the conditions must be favorable, and these conditions are rest and exclusion from light, until all the carbon compounds are burned out and transformed into new substances by their own decomposition. If bob veal, which is the meat of a young calf, is exposed for sale, such exposure constitutes a crime and the offender is punished for breaking the law. Why is it accounted a crime? Because very young veal is not fit for human food. The very same rule should apply to the exposure for sale of very young whiskey. Like the veal, it will be fit for consumption by and by, when it grows older—age is the factor in both cases. It may here be stated without the likelihood of contradiction that if whiskies were properly ripened before being exposed for sale in distilleries and saloons, two-thirds of the crimes and four-fifths of the insanity charged to the account of alcohol would disappear from the indictment, so bulky and terrible, that stands against it on the statute books of society. It is the quality of the alcoholic product, not its quantity, that should be considered, and, if the quality is right, the quantity will regulate itself. [The author here kindly and respectfully directs the attention of this august assemblage, which he has the honor of addressing to-day, to this fact, and requests that it gives it the thought a subject of such importance deserves, being, as it is, a matter affecting a large part of the community, and from whom we derive most of our livelihood.]

Alcohol as a General Stimulant and Heart Tonic.—The question whether alcohol is a food has for a long time been discussed *pro* and *con* by writers on materia medica and therapeutics and by the expositors of social economics, but until recently no definite answer has been given, as most of the writers started out to prove that their side of the question was of necessity the only correct one. This was conspicuously the

case with so-called temperance doctors and prohibitionists; for this reason their investigations had no scientific value, and consequently were worthless. They denied with vigor that alcohol had any food qualities, later they further denied that it had any stimulating properties other than that which it excited as an irritant. It is hardly necessary to say that this latter assertion is not worth refuting, for, in order to have produced the pathological phenomena so well described by themselves and admitted by all writers, it must first have excited and aroused into activity the stomach and circulation. This an irritant cannot do. Alcohol may after its local effect continue its action as a depressant and narcotic.

Standard medical writers, however, have always taken the position that alcohol stands first in the select class of substances that may be rightly admitted to be general stimulants and heart tonics. They also go a step further and assert that it serves as a food in certain states of the body in health and nearly always when the body suffers from disease, and for that reason is a useful adjunct to the repertoire of the physician in his daily professional rounds.

The human body is largely sustained by organic compounds, chief among which are the hydrocarbons. These hydrocarbons are known to yield up alcohol under conditions that can be presented in the chemical laboratory of the body. There is little doubt but that all hydrocarbons ultimately offer their nutrition to the tissues, and distribute their heat to the body in the form of some alcohol, with the formula of which we are not acquainted, and never may be. Some experiments recently made with the object of determining definitely whether alcohol is a food have been conducted along lines mapped out by the ablest writers on therapeutics, and drawn from careful observation under a variety of conditions, clinical and empirical. These writers felt sure of certain facts, *viz.*, that alcohol under definite conditions acted as a food, in fact, that it was a food; but scientifically they were not able to establish this conclusion, for science must always be the standard by which to measure every form of investigation and the key to unravel all phenomena whether of mind or matter.

Through the experiments conducted by Professor Atwater it has been proved that alcohol is a food and that it yields up its heat and force exactly as does a pound of bread or a bowl of soup; and that it best does this under circumstances that render it impossible for either of the others to have any value as a food supply.

Alcohol differs from all substances in one essential particular in that it presents allotropic features with varying conditions of the body, acting as a stimulant, a tonic, a food, an irritant, or a poison. When we wish to form new compounds from the elements of others there is a favorable moment, known as the nascent condition, when the elements are dissolved and at liberty to choose new affinities.

The human body, no doubt, presents such a condition to the oxidized hydrocarbon compound, alcohol, at a time of fatigue, disease or hunger, in the order in which they are written. At such time the affinities are feeble and present the favored moment for the transformation of the alcohol into heat and force. Under ordinary conditions, however, the natural stimuli of the body are food and oxygen; they are expressed in the phenomena of vital activity, the measure of which is volition and sensation. In the healthy human body, when not suffering from exhaustion or shock, food, rest and oxygen supply the most favorable conditions for its maintenance and growth.

If the average physician could look at alcohol in the abstract, view it as he would a pile of lumber or a heap of sand, a thing capable of being applied to a certain purpose or under changed conditions to a number of purposes, the objection to its use, when it could be useful, would quickly disappear. Is it logic for one to object to sand being used in the building of the house because a friend, while excavating, without taking the proper precautions, was overwhelmed; or to be opposed to the use of wood in interior decorations because a careless man was killed by a falling timber? Such a course of procedure would not be rational ground for objection.

Electricity has torn the earth asunder, rent the air and made the heavens awful with its lurid flame; it has ravaged the face of nature and created havoc and desolation in every land and clime on the habitable globe, destroying many thousands of lives every year, yet on that account nobody objects to it as a fuel nor as a light to illuminate his dwelling. While we recognize the danger of electricity, we are prepared to utilize its useful and economic side and adopt it as a valuable household auxiliary. To condemn and repudiate it because it kills its thousands every year is like denouncing alcohol because it destroys those that abuse it. Electricity in the kitchen, in the parlor, the counting-room and the physician's office produces comfort and lightens life's burden. Alcohol in the banquet-hall, in the beer-garden and at the domestic hearth makes thousands merry for every ten it renders miserable and for every one it destroys. The man is justified, who, feeling insecure, puts up a lightning-rod to protect his house, and the man who cannot handle alcohol in a rational manner is equally justified in taking a pledge and attaching himself to a temperance society; but he has no right to denounce alcohol because of his own weakness any more than he should a lamp-post which he was unfortunate enough to run foul of when under the influence of his potation. The lamp-post, serving a useful purpose, had a right to be where it was. The alcohol, too, was prepared to serve a useful purpose, but the man who imbibed it freely robbed it of the opportunity to put its purpose into practice.

To recognize the properties of alcohol in the abstract, and to know that it has other purposes than to make men intoxicated and disorderly,

is the duty of every physician. He must see alcohol from its useful, and health-giving point of view, and not from that of the clergyman or the temperance orator, the former of whom may know nothing of alcohol—the latter, too much. These men, undoubtedly, are honest in motive, and are justified in their harangues and philippics against alcohol, because they are looking on its moral side and entirely incapable of seeing any other, although there are several and all in plain sight of those who are not carried away by the excitement and prejudice aroused by the men who are looking on but a single side.

It is difficult to contemplate without pity the position of these poor men—the clergyman and temperance lecturer, with the few friends they have gathered round them—conscripts from the medical profession and others assembled in the moral blockhouse, unconscious that no war exists, but who are fighting for principles that have been conceded and deaf to the bugle blast of common sense which demands reconciliation and reunion as a common benefit to all.

The Physiology of Alcohol.—An important side of alcohol, and one that should have interest for every physician, is the physiological one. As a physician, this side should interest him most, as it has especial value in the time in life when the fire on the human hearth is burning low and the powers of life almost exhausted. Another, the pathological side, will be touched on when we come to speak of alcohol in disease.

When the human body is free from pain and every organ in the vital mechanism performing its function after its order, the body may then be said to be in perfect health and its measure of vitality might be rated at a hundred. There are many fluctuations in this human barometer and it may sometimes fall very low in case of great and prolonged muscular and mental exertion, actually down to fifteen, or even ten, the body being in perfect health; if it were otherwise, as is the case of disease, no such low-water mark could be reached, as death would speedily ensue. The body in this enervated state is suffering from the effects of extreme exhaustion and must not be confounded with the collapse occurring at the critical stage of a disease.

The body suffering from extreme exhaustion is in the position of a bank which has paid out the last dollar of its working capital to stop a run and avert a panic. It has securities in the shape of potential energy locked in the muscles but they cannot be got at to be turned to immediate account. Rest and sleep would solve the problem and liquidate the human bank, but this is now out of the question, for aid must be immediate. What can give this aid? Can anything liberate and transform the force tied up in this exhausted man's muscles into a working capital of dynamic energy, so that the body may perform its function and he finish his task or journey at once? Anything that will do this will be acceptable to him, and the thing which will do it quickest will be most acceptable. What is that thing? Most undoubtedly alcohol. In this dire emergency, alcohol turns its physiological side (like a mother her breast to her hungry child) which here has two offices, the one to develop energy in exhausted tissues, by the heat it yields up through its own oxidation; the other, by its stimulation, to equalize the blood current which is irregular and deficient at the periphery of the circulation.

The man who walked yesterday twenty miles in five hours, and, who, while not yet at the end of his journey, grew weary and exhausted and unable to proceed further; that this journey should be completed in a given time means all to him; four miles have yet to be covered and he is exhausted. What can he do to enable him to complete his journey? He is a temperance orator, besides being a lecturer on therapeutics in the college of a New England town, but, for the time being, has adopted the vocation of a pedestrian; he knows all about the use of alcohol, as he does the virtue of drugs, but none of his drugs have helped him now; beef-tea and coffee in turn he has tried; they have failed, although so potent in the early hours of his journey, for now they have irritated and upset his stomach, making it as weak as his legs on which he can hardly stand and utterly unable to digest any substance, fluid or solid. This is a moment of anxiety for that therapeutic pedestrian, as the completion of his journey in a given time means a world to him. His stomach is wholly useless and unfit to perform any function (in fact it pains him), being as unable to digest as an elephant is to fly. Its muscular coat is paralyzed and its mucous layer irritated and lying collapsed on the viscera like a torn balloon on the turf. He does not believe in whiskey and says so in his lectures to the students at the college, declaring it to be an irritant under all circumstances, a depressant and a poison, but, at the urgent solicitation of his trainer, who is a professor of physical culture at the same college in which he has the honor to fill the chair of therapeutics, he is persuaded to take four ounces of old whiskey, which the trainer has handy in a flask. After thus imbibing, he finishes the remaining four miles of his journey with an ease and grace that appear to be born of magic.

A man, loitering in a saloon the other day, drank four ounces of whiskey, after which he became so intoxicated that it became necessary to remove him to a hospital, where he died the same evening. Another man, a physician, after successfully terminating a difficult labor case, drank eight ounces of brandy, after previously administering ten ounces to his patient, who was exhausted from postpartum hemorrhage; its timely administration saved the woman's life; the only effect it had on him was to readjust his disturbed circulation, equalize the nervous current in life's dynamo that was rapidly burning out the switchboard of his vitality, and restore the mental coordination lost by his great exertion. He was not intoxicated, neither was his patient, by their large potations, although twelve hours afterward, when recuperated from their fatigue, the same

quantities would be followed by unconsciousness and probably death, when a beautiful illustration of the pathology of acute alcoholism could be exhibited on their cadavers. The only effect on the brain was a slight stimulation of the cells, producing a pleasant exhilaration. The alcohol in both cases was immediately burned up like a handful of shavings in a blast furnace, to fill a physiological demand by yielding up its heat to warm the body and by destructive metamorphosis liberating energy by its vitalizing power from enfeebled and paralyzed muscles. It thus enabled the heart to perform its function and the man to continue his existence.

(*To be continued.*)

CLINICAL MEMORANDA.

THE THRUSH-FUNGUS AS A CAUSE OF GASTRITIS.

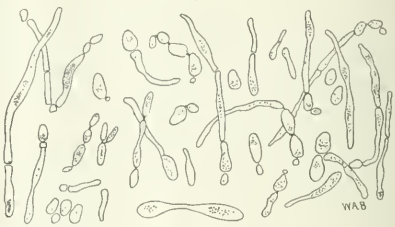
By W. A. BASTEDO, Ph. G., M.D.,
OF NEW YORK.

It is well known that the thrush-fungus (saccharomyces albicans, Van Tieghem; oidium albicans, Robin) is responsible for many cases of sore mouth, and has been reported as causing various inflammations in other portions of the alimentary tract. From Europe we hear of a few cases of acute gastritis due to this fungus, yet in this country a "thrush" gastritis is so rare as to be a medical curiosity. One of these cases was admitted to the service of Dr. A. A. Davis, at St. Luke's Hospital, New York, last summer and gave the following clinical history:

Miss F., aged twenty-six years; she has always lived in New York; occupation, light housework. She gives no previous history of any sore mouth, or stomach or intestinal trouble; has been very healthy up to her present illness, has never used alcoholic drinks, but for several years has consumed large quantities of coffee. On August 5, 1899, the patient was apparently in her usual health in the morning, but in the afternoon had a severe chill, which was followed by persistent vomiting. She had a severe frontal headache, which continued for two days. Abdominal pain was absent until one and a half days after the onset of the vomiting, when she felt a sudden sharp pain just below the ensiform cartilage. This pain and the vomiting continued severe until the time of admission to the hospital, ten days later. Since vomiting began she has been unable to retain anything in her stomach, even a small amount of water being rejected within five or ten minutes after swallowing. At no time did she vomit blood of coffee-ground material. The lips and tongue have been dry and sore, her bowels constipated, and her urine scanty and dark-colored. She has the sensation of a "distinct lump" below the ensiform cartilage. Occasionally she belches gas, but without any relief from the pain.

A physical examination eleven days after the onset of the symptoms shows a small anemic, emaciated patient. Her tongue is red, dry and cracked. The lips are dry and with slight herpes in the left angle of the mouth; pupils are normal; lungs and heart negative; radial pulse regular, rapid, with some tension; artery moderately thickened. The liver is felt just below the free border of the ribs; the edge is soft, but not tender. The spleen is not enlarged. The lower border of the stomach percusses on a level with the umbilicus; there is marked tenderness and resistance in the central epigastric region, but no mass can be detected. Genito-urinary organs negative. Temperature, 99.4° F.; pulse 128, respiration 28. The patient was much prostrated and vomited twice while being examined. The vomitus consisted of clear fluid containing a little mucus and many grayish particles which floated on the surface and looked much like an ordinary mould. A chemical examination of the fluid showed no free hydrochloric acid, no bile, no maltose, traces of organic acids. Under the microscope the grayish masses were seen to consist of a few bacteria and epithelial cells, probably a few yeast cells, and a large amount of the saccharomyces albicans or "thrush-fungus." At this time the patient's leucocytes were 12,600 per cmm.; her urine dark-colored, of specific gravity 1022, and containing a slight trace of albumin and very few hyaline and granular casts.

Fig. 1.



The Thrush-fungus (saccharomyces albicans, Van Tieghem).

She was given a nutrient enema consisting of the yolk of one egg, peptonized milk ʒvi, beef peptonoids ʒii, whiskey ʒi, with a pinch of salt. This was at once expelled. Lavage was resorted to and a large amount of the fungus removed. Milk with cerium oxalate and sodium bicarbonate was given through the tube, and was vomited in curd a few minutes later. Then a dose of codeine, one-eighth of a grain, and chloroform water, one dram, was given and followed in five minutes by milk and lime-water, one ounce of each. This was retained and the procedure was repeated every two hours with success. The next morning, as she was somewhat better, an Ewald-Boas test-breakfast, consisting of a roll and 360 c.c. of weak tea was given, and it was retained, although there was some nausea. It was evacuated one hour later. A few cubic centimeters of thick fluid was obtained, containing much undigested roll, some mucus, and much of the fungus. There

was no free HCl, but a small amount of combined HCl, traces of lactic acid and of the acids of fermentation; total acidity 20. There was no bile, starch-digestion was moderate; the rennet-ferment was abundant. The mixture of codeine and chloroform was omitted on the second day and two ounces of milk with sodium bicarbonate given every hour. This was retained. On the fourth day, the morning lavage showed no fungus, and the patient began to have an appetite. Broths and a scraped-beef sandwich were taken with relish and with no discomfort. Five days later the patient was walking about and eating regular meals.

The size of the liver remained the same throughout. On the day after admission menstruation began and was normal in amount and duration. A careful examination and cultures taken failed to reveal any infection of the mouth and throat. As there was a large quantity of the fungus in the stomach, and as no other etiological factor could be ascertained, thrush would seem to be the probable cause in this case.

In the literature there is no satisfactory statement as to whether the fungus grows free in the stomach, or is attached to the walls, or penetrates the stomach-cells. It is also not known whether the fungus develops very rapidly, producing gastritis in a very short time, or whether its growth is slow, and it gradually accumulates until the stomach is no longer able to tolerate it. If the latter is the case we would expect some prodromal symptoms before the acute onset. The specimens obtained by us indicate that the fungus was undergoing rapid growth. Morphologically the globular and globulo-filamentous forms predominated and these are the forms obtained in the laboratory by rapid growth in favorable media. The filamentous forms tend to develop in media of complex chemical nature; or, where the growth of the fungus is retarded, as in the presence of antiseptics.

A CASE OF TRANSVERSE PRESENTATION; DOUBLE UTERUS.

By A. H. HAYDEN, M.D.,
of Summerville, S. C.

As I deem the case I am about to report one of interest to practitioners generally and worthy of report for statistical purposes, I submit the following history: On January 1, 1900, at 9 P.M., I was called three miles in the country to Mrs. D., white, aged forty years; multipara; ninth pregnancy. She had been in labor thirty-six hours. On examination I found the left arm of fetus protruding from the vulva, dorsoposterior position, with head to the left side and the shoulder completely wedged. All movements of the fetus had ceased, and labor pains were infrequent and very feeble. The woman had been in the hands of a so-called midwife, who informed me that the condition which I found existing on my arrival had obtained since 9 A.M., the woman having had rapid and violent pains from that hour until shortly before my arrival, at 10 P.M. A glance was sufficient to show that the woman was in a state of collapse. Examination revealed no radial or temporal pulse and the second sound of the heart was not to be recognized. The abdomen was excessively tympanitic. Hypodermics of digitalis and ether and later of nitroglycerin failed, after a lapse of twenty minutes, to induce the slightest response from the heart, so without the use of anesthetics I proceeded to perform podalic version and deliver with some difficulty. One knee was reached, but not without the introduction of a portion of the hand into the uterus. By careful and continued manipulation a foot was soon brought down. This being accomplished delivery was easily effected. Fearing the occurrence of post-partem hemorrhage, a full dose of ergotole with one-fourth grain of morphine was given, after version and before delivery was completed. As it was evident that the fetus had been dead several days no effort was made toward complete delivery until uterine contractions, which were very feeble at the time of delivering the lower extremities, were of the strength and regularity approaching the normal. The third stage of labor was disappointing, inasmuch as every effort of nature, as well as those of my own, failed to expel the placenta. This was finally accomplished, but not without reluctantly, although of necessity, passing the hand within the uterine cavity. Throughout the whole process of delivery the patient's condition manifested no appreciable change. Shortly after delivery her general condition seemed improved, but at no time for three and a half days was there a return of the pulse. After this, until her death, which occurred on the morning of the tenth day, her general condition improved slightly, and her pulse, although recognizable and regular, was very weak. For three days following delivery there was great tympanites, but little or no tenderness over the abdomen, which was tolerant of considerable pressure save over a small area of about two square inches directly above the symphysis, nor was the tenderness very marked even here. Tympanites entirely disappeared by the end of the fifth day. The patient's temperature on the second day reached 100° F., but at no time before or after was it above 99° F. There was no hemorrhage at the time of delivery, or after. I was informed by attendants that there was little or none before my arrival. The placenta was already detached when efforts were made to remove it and had evidently been so some time prior to delivery. With the placenta two large clots were delivered. Lochial discharge was scant for forty-eight hours, but later was normal in character and amount. The urine had to be drawn with the catheter fourteen hours after delivery, but after that was passed by the patient at regular intervals, and, as nearly as could be learned, was normal in quantity. In appearance the urine was normal, save perhaps slightly high colored. It contained no albumin. The bowels were constipated for two days, but responded kindly to a

dose of oil, which was followed by normal, daily evacuations. From the time of delivery to the time of death the patient complained of extreme weakness, although constantly insisting on the necessity of sitting up, and taking solid food, both of which privileges were denied her. When I saw her last, twelve hours before her death, she was apparently doing well, although still on heart tonics, stimulants, and liquid diet, and complaining of "awful weakness." She died rather unexpectedly, at 4 A.M., on the tenth day, her attendants reporting that she had been extremely drowsy from 6 P.M., and at the last had "slept soundly and never waked up," her end being quiet and painless, and her mind, during waking hours, perfectly clear to the last. For two days prior to her death she passed her urine and feces in bed, apparently involuntarily, although at the time she would converse rationally and state to her attendants what had happened. The patient belonged to the poorest of the poor class, and her surroundings were such that worse are scarcely ever seen. The proper medicines were provided for her, however, and nourishment. Her death I can only attribute to exhaustion, from which she never rallied, although she survived her labor for a fraction over nine days. After her death I was informed that at about 5 P.M. on the day of her death she had, at her earnest solicitation, been allowed to sit up in a chair for an hour or more by her attendant. She had experienced no difficulty in any of her eight previous labors. During the entire summer and up to the time of her confinement, she informed me, she had been having malarial paroxysms at regular intervals.

The double uterus in this case is of interest. After passing my hand into the vagina in my first examination, I noticed that the examining finger, following as closely as possible, the line of the arm to the point of the shoulder, lost contact with the arm. Pausing a moment to ascertain the cause, I found between it and the arm tissue which was recognizable as uterine. Thinking that I had met with a cervical laceration and that a flap on one side of the rent had insinuated itself between my finger and the arm, I tried to again make digital contact with the arm without withdrawing my finger. This I could not accomplish, and in a moment I discovered that my finger was within a circular aperture separate and distinct from the orifice through which the fetal arm was protruding. I then quickly, but thoroughly explored the opening as high up as it was possible to reach with my finger, found that it terminated in a cavity something more than a finger's length in depth, comparatively smooth internally, and without any opening to be detected, save at its vaginal extremity. My finger was freely movable in it and I could, through its inner or right lateral wall, make out distinctly the outlines of the fetal head, while its left or outer wall was, to the touch, very much thicker and more resisting. I now recognized that I was dealing with a case of double uterus, and determined if possible later on to further investigate the matter. After turning the fetus, which was in the right uterus, and while still only the lower extremities were without the os, I passed my finger again into the opening to the left. The uterus was still comparatively inert, and I was able to pass my finger quite two-thirds of its length into the cavity, at the same time keeping my left hand on the woman's abdomen awaiting the next appreciable contraction. After waiting thus for probably a minute there was quite a strong contraction and simultaneously as the impulse was conveyed to my hand on the abdomen, the tissues surrounding my index finger in the vagina contracted forcibly around it. This dispelled all doubts that might have existed concerning the nature of the second and smaller cavity. When delivery of the fetus had been accomplished, and I found it necessary to pass my hand into the uterus to extract the placenta, I took occasion to note carefully anything out of the normal in such cases which might present itself to the touch. During this manipulation I found that the two uterine openings were distinct and separate at the os externum and that at this time the finger could not be inserted in the left (unimpregnated) uterus for more than an estimated half-inch and that the margin of each external os was complete in itself save the partition common to both. The partition tissue separating them was considerably less in thickness and softer in consistency than the opposite (left) and unimpregnated side, and slightly thicker than the impregnated (right) side of the uterus. With the hand in the impregnated uterus I noted that the right partition wall of the cavity was thick and resisting and seemed to bulge somewhat into the cavity, while the balance throughout seemed to be much thinner than the normal. This examination, although very hasty, was carefully made with the aid of the left hand on the abdomen while the right was within the uterus.

MEDICAL PROGRESS.

Cold Bathing in the Treatment of Typhoid.—J. C. Wilson and J. L. Salinger (*Phila. Med. Jour.*, March 3, 1900) give complete and full statistics of 1904 cases of typhoid treated by them by the Brand method of cold bathing or by modifications of that method as gradually adopted. The mortality of the 1904 cases was 7.5 per cent. The writers make the following affirmations, based on the full statistics of these cases: (1) That the treatment by systematic cold bathing does not avert or diminish the frequency of hemorrhage. (2) That the frequency of the occurrence of perforation is diminished. (3) That it diminishes the danger of complications, especially those relating to the circulatory and respiratory tracts. (4) That it is apparently attended by a somewhat increased frequency of relapse, although general statistics in regard to relapses are entirely unsatisfactory. If relapses are more common in bathed cases it is probably due to the fact that owing to

the reduction in mortality a large number of cases which under other forms of treatment would have died in the primary attack survive to suffer the relapse. (5) That the treatment is attended by the occurrence of albuminuria in a large percentage of cases. This albuminuria shows itself in two forms: (*a*) As a faint reaction without casts or other indications of renal disease; (*b*) cases in which albumen is present in considerable amounts with blood-corpuscles and casts. (6) That it has no influence in increasing the danger of otitis media. The writers have gradually modified the original method of Brand, as follows: (1) Purgatives are administered early in the attack. Calomel is used for this purpose in fractional or large doses and is sometimes followed by a saline. Purgatives are never given to cases after the tenth day of the attack. (2) Cold compresses or ice-bags are applied to the abdomen in all cases of abdominal tenderness or pain, and in hemorrhage. Turpentine stupes are also applied for tympanitic distention of the abdomen. (3) Evidences of hemorrhage, perforation or peritoneal infection contraindicate systematic cold bathing. Cold bathing is instituted in all suitable cases, but drugs are used as each case requires. Only about ten per cent. of the cases require any medication whatever, except the early purgatives, throughout the disease. (4) During the whole course of the attack whenever, three hours after a bath, the temperature in the axillar reaches 101.4° F. the bath is repeated. (5) Baths are continued after the temperature has ceased to rise to 101.4° F., during defervescence once or twice a day and for a short time afterward once every one or two days. (6) Instead of having them lifted from the bed into a tub beside the bed, the writers have encouraged the patients to help themselves. Grave cases were lifted into the tub, but as their condition improved, and in other cases, they were encouraged to help themselves and were soon able to enter the tub with but little assistance. Then a stationary tub was placed at the end of the ward and the patients, with assistance, walked every three hours to the bath and back to the bed. The most distant bed was six meters from the tub. The severest cases were placed nearest the tub and were carried to the tub until able to walk. This procedure was found to exert a very favorable influence upon the course and symptoms of the attack. In over three years the writers have had 776 cases bathed in this manner, with a mortality of 7.8 per cent. The regular and slight exercise of the muscles every third hour, and the stimulation to the system tends to relieve the passive congestion of the viscera and thus minimizes certain of the pathologic processes. (7) To be of benefit the cold bath must be given early and systematically. The favorable results of cold bathing are due to the rhythmic repetition of the stimulation of physiologic processes and of the modifications of pathologic processes brought about by a succession of baths begun early in the course of the disease.

Intestinal Sand.—R. S. Thomson and A. R. Ferguson (*Jour. Pathology and Bacteriology*, Feb., 1900) complete a preliminary communication made before the Clinical Society of Glasgow on an unusual case of intestinal sand occurring in a woman of thirty. She had suffered at intervals of several years from symptoms of catarrh and moderate dilatation of the stomach, associated at times with signs of decided neurosis. Decided constipation was the only condition that drew attention to the intestines. The patient was kept at rest and fed on small quantities of milk, with occasionally fish and toast. Lime-water was also given with the milk. While the diet was confined to milk and lime-water it was observed that considerable quantities of sandy matter were passed at each defecation. This same kind of sandy material had been passed for several months prior to the time of reporting. The sandy matter was heavy, sinking rapidly to the bottom of the vessel, brownish-yellow in color and resembled uric acid quite markedly, both macroscopically and microscopically. The crystals were, however, quite irregular in form and the tests for uric acid were all negative. The sand was not of vegetable origin as a microscopical examination showed. Chemical analysis revealed 25 per cent. organic matter and 75 per cent. inorganic matter, of which there were 11 per cent. calcium carbonate, 87 per cent. tri-calcic phosphate and 1 per cent. silica. The sand was unchanged by hot or cold water, alcohol, ether, chloroform or any of the usual solvents, but it was readily dissolved in weak acids. The coloring pigment was of interest in that while closely related to many of the well-known pigments of the body, yet it was distinct and the authors believe that it represents a substance intermediate between the ordinary bile pigments and their ultimate product, stercobilin. The ready solubility of the intestinal sand in dilute acids suggests that it was formed, neither in the upper part of the small intestine, where practically unchanged bile pigments are present, nor in any part of the colon, in which stercobilin is the prevailing pigment, but in the ileum, where the intestinal contents are most liable to be alkaline in reaction.

New Blood Parasite.—It is not often that in a journal of high scientific repute one finds details of new discoveries which bear the ear-mark of bad observation. Von Tunzelmann (*Jour. of Pathology and Bacteriology*, Feb., 1900) describes some remarkable parasites found in the blood of Chinese suffering from a disease which he says is common to that country. The parasite is classed as one of the molds, with branching hyphæ and numerous spores. The hyphæ are described as being ½ to ¾ of an inch in length, as they emerge from the capillaries, the illustrations apparently making them out to be much wider than the ordinary capillaries of the finger. The precise technic is not given, but it may be suspected that the blood was examined in a contaminated solution of some sort, either the ordi-

nary salt solution or the staining fluids were contaminated with one of the common molds. The author says that every one has them. Even the gravy of hot roast-beef abounds with them. If editors of scientific periodicals cannot shield the non-technical student where will such pseudo-science, such as this appears to be, bring us?

Apomorphine as an Hypnotic.—Authorities on materia medica usually state that apomorphine has no hypnotic or narcotic action. Considerable experience with the use of this drug has induced C. J. Douglas (*N. Y. Med. Jour.*, March 17, 1900) to believe that there is no remedy so near an approach to an infallible hypnotic as apomorphine, and he has found it equally useful in all forms of insomnia regardless of the cause. It should be given in a single dose of about one-thirtieth of a grain, injected subcutaneously. The object is to give a dose that, on the one hand, is large enough to produce sleep, and, on the other is so small that nausea and vomiting are avoided. Hence, individual susceptibility must be considered. It should be given when the patient is in bed, for its effect is very rapid and the patient will usually fall into a restful sleep within five to twenty-five minutes. If no results are observed within one-half hour the dose is too small. The effect persists for from one to two hours, but in many cases of insomnia the patient will sleep all night. In active delirium it acts very well and a slight nausea may increase the effect in those cases. There is no possibility of a "drug habit," for it becomes a vigorous emetic if the dose is increased.

Therapeutics of Heart Disease.—The indications for treatment in the various acute and chronic conditions of the heart are reviewed in a valuable article by W. H. Thomson (*Med. Record*, March 17, 1900). The routine fashion of treating nearly all cardiac troubles with digitalis is thoroughly deprecated. The acute disorders he divides into those of an inflammatory character and those due to a parenchymatous myocardial degeneration, secondary to diphtheria, the acute exanthemata, or sometimes appearing in cases of rheumatism. Overstrain may produce an acute condition with its symptoms and indications for treatment differing from the above, and this may occur not only in healthy hearts but also from injudicious exertion in convalescents from typhoid. In the acute inflammatory states the condition is one of great excitement of the viscus, and rest is, therefore, one of the most imperative indications. When the heart is beginning to fail in acute cardiac inflammations, as the pulse, dyspnea, and other signs develop, it is from an overfatigue which in the majority of cases will only be aggravated by administering heart stimulants. With febrile temperature, cardiac pain, hurried respirations and rising pulse with distended rhythm, the treatment should be leeches to the pericardium, followed by constant poultices of flaxseed-meal with extract of hamamelis and laudanum poured on just before the cataplasm is applied, and then covered with oil-silk continuously, day and night. He believes that no vascular sedative is so potent as bloodletting which acts reflexly through the surface nerve impression. The poultices act similarly, since there is a most intimate vasomotor association between the nerves which control the blood-vessels of the viscera and of the corresponding skin areas above them. The drug which is the ideal heart sedative in all such conditions is aconite, since it promptly alleviates cardiac pain and shows the heart beats, which is the important indication. A strong laboring heart impulse and a rapid pulse demand aconite rather than digitalis.

Where high tension exists veratum viride is much better than aconite. In cases of acute parenchymatous degeneration secondary to diphtheria or the exanthemata, surface pallor is the characteristic hue and the pulse is rapid, small and irregular. Digitalis is here a most mischievous agent. Its action is to diminish the size of the heart's cavities and is of great service when the heart walls are overdilated, but the important fact about digitalis is that it must have a normal muscle to act upon, and is, therefore, a harmful drug in these cases. Alcohol, however, should be pushed to its utmost limits with strychnine, caffeine and hypodermic injection of camphor, gr. viii; to sterilized oil, ♏xx. These remedies are also indicated in acute carditis when the heart begins to fail, and should be substituted for aconite when the heart is beating feebly instead of strongly and when the extremities become cold rather than hot. Many of the chronic sequelæ of acute endocarditis could be obviated by a prolonged convalescence, which is strongly urged, in order that the progressive involvement of the valves may be arrested as soon as possible. Prolonged rest and aconite furnish the greatest safeguard. Considerable stress is laid on myocardial degeneration, which the author believes to be one of the commonest and most efficient of all causes of failure of compensation in the heart disease of patients after middle life. It precedes valvular lesions in a large proportion of cases. In the treatment of chronic heart disease, all organs of the body which have to do with nutrition must be called on to do their share. Digitalis is here often of inestimable value, especially in cases of dilatation subsequent to hypertrophy, but it is important to realize that mercurial laxatives are most effective adjuvants to this drug. Half-ounce doses of the infusion are preferred, for which is substituted in a few days thirty drops of a mixture of equal parts of the tinctures of digitalis, strophanthus and nux vomica. When digitalis is not well borne, a very good pill may be given, composed of spartein sulphate, gr. i; powdered squills, gr. ss; caffeine citrate, gr. iss, and strychnine, gr. $^1/_{30}$. Permanent improvement, however, is to come from other agents and measures which restore nutrition rather than stimulate function. Too great reliance must not be placed on drugs. Fresh air and systematized exercise are extremely important. Iron, mercury, the

iodides, and arsenic are oftentimes of great service as systemic tonics. Ortel's mountain-climbing, massage and Schott's saline and carbonic-acid baths are excellent in principle and very effective when adapted to certain cases.

Whooping-Cough.—A number of statistics have been deducted by W. A. Dunckel (*Med. Record*, March 17, 1900) from the two hundred and sixty-one cases of whooping-cough which appeared at the New York Dispensary from 1894 to 1900. The records of these cases are, of course, oftentimes very meager. In point of frequency, sixty per cent. were females; sixty-seven per cent. occurred between the ages of six months and five years. There were but two cases at three months and none later than ten years. Complications were noted in sixty-seven per cent. of cases and were divided into two groups. (1) Those dependent upon the violence and strain of the paroxysms, and (2) those due to lesions associated with the disease. Of the first group there were: Hemoptysis, 6; epistaxis, 2; subconjunctival hemorrhage, 1; umbilical hernia, 2; ulcer beneath the tongue, 2. Of the second group there were: Mild bronchitis, 2; severe bronchitis, 33; bronchopneumonia, 19; tuberculous meningitis, 1; pericarditis, 1; malnutrition and wasting, 8. Four cases terminated fatally, three being due to bronchopneumonia. Relapses were noted in five patients. Emphysematous changes were subsequently observed in only a few patients. It is surprising that tuberculosis is not a more frequent complicating condition. Not one of these cases while under observation had any endocardial complication, nor was it possible to be satisfied that there was any cardiac enlargement. Belladonna was sometimes used to allay the paroxysms, but the most reliance was placed upon a supporting treatment of cod-liver oil and malt preparations.

Influenza and Meteorology.—A few interesting facts are given by J. Ruhemann (*Berl. klin. Woch.*, February 26, 1900) à propos of the epidemics of influenza which have been raging in the German cities this winter. He asserts that the only meteorological factor in these epidemics worthy the name is the sun. This body's antibacterial and germicidal influences are well known especially in their bearing on the infectious diseases. Thus in Berlin, the smallest quantity of sunshine measured by the meteorological bureau since 1893 was registered during the month of January, 1900. For the entire month, the sun shone but 0.8 hours. In 1899, Berlin had 62.3 hours of sunshine during January. During the month of December, 1899, notwithstanding the shortness of the days of this month, the sun shone for 19.0 hours—more than twice as long as during January last. In Magdeburg, a similar state of affairs existed. Since 1882 the least sunshine for January was recorded for this year, when it reached 19.0 hours for the entire month. In 1899 it was as high as 69.0 hours for the same month. In Breslau the sun shone but for 7 hours for the entire month of January. The author further states that the 9.8 hours of sunshine in Berlin occurred before the fifteenth of the month, no sunshine at all brightening the town for the remaining days. It was just in this latter half of the month that the grip epidemic became so severe and far-reaching. In 1889 the last extremely severe epidemic occurred. During that year, in January, there were 23 days in which the sun did not shine at all in Magdeburg and 22 days in Berlin. Ruhemann believes that these facts warrant his conclusion of the dependence of the influenza germ upon the absence of sunlight.

Constitutional Albuminuria.—This name is suggested by F. Martin (*Klin. therap. Woch.*, March 4, 1900) as better expressing the presence of albumin in the urine without nephritis than the older names, cyclic or physiological albuminuria. No doubt the condition is a pathologic one, depending most likely on a congenital weakness of the glomerular epithelium which, from the mere strain of being up and about, allows albumin to pass. The disease may disappear or gradually pass into a true nephritis, but experience is as yet not sufficiently great to determine to what percentage the latter ever takes place. The relation of the disorder to organic renal disease is the same as that of alimentary glycosuria to true diabetes. It is important to be on the lookout for this form of albuminuria, for the condition is by no means rare, and children who easily tire at school, suffer from headaches, perhaps are troubled with heart-weakness, must be regarded with suspicion. It would seem that the best treatment, in addition to avoiding the use of alcohol and other irritants, would be to keep these patients in bed. They do not, however, feel sick enough for this and a prolonged rest only demoralizes. Hygiene measures and careful training are the chief mainstays. Often the abnormality corrects itself, and the author has seen a case go through pregnancy without untoward results.

Opening Pericardial Sac.—C. Ogle and H. Allingham (*Lancet*, March 10, 1900) noticed during an operation for suppurative pericarditis that the heart's action was not interfered with by rubbing off fibrin from its surface, but that it was actually improved. Since these fibrin patches interfere with drainage and tend subsequently to form adhesions, it is important to know that the heart may be handled rather freely without danger. By the ordinary operative route one can not reach the base and posterior aspect of the heart to clean thoroughly, and often the pleura is injured and may be infected. To get at all sides of the heart and to avoid damaging the pleura, they devised the following operation: A three-inch incision is made from the costo-xiphoid angle along the lower border of the left seventh cartilage, which is then exposed by separating the abdominal muscles from it. It is then pulled upward and outward to expose the lower surface of the diaphragm and the cellular inter-

val at the costoxiphoid angle, through which a good-sized opening is made. A mass of fat is exposed in the space between the sternum, diaphragm, and pericardium. This fat is pulled downward with the diaphragm, when the pericardium presents itself, and can be freely opened below and in front, and a finger inserted to explore the entire sac and remove fibrinous masses. The peritoneum may be exposed early in the operation, but is pushed away without damage as in suprapubic cystotomy. The method has the following advantages: No possible damage to pleura; drainage from the most dependent part of the sac, through a large opening not bounded by cartilage or sternum; ease and efficiency in exploring and cleansing the heart. In certain cases with rigid cartilages, it may be necessary to resect a portion of the seventh cartilage.

Terpinol in Hemoptysis.—In the continued bleeding of tuberculosis, F. G. Janowsky (*Klin. therap. Woch.*, Feb. 25, 1900) has found terpinol far superior to the usual remedies. After eight to fifteen doses of 3 drops each, given at short intervals, the hemorrhage in most cases ceased. If no improvement follows after thirty-six hours, the drug had best be discontinued. As compared with turpentine, terpinol easily ranks first. Albuminuria or hematuria never followed. Occasionally a slight burning in the pharynx is complained of, which can easily be prevented by giving the drug in some demulcent.

New Hernia Suture.—L. Freeman (*Annals of Surgery*, March, 1900) describes his hernia suture. When ordinary material and methods are used, a suture, once the wound is infected, must come away before complete recovery can ensue. Even with primary union a late, sluggish inflammation, causing a sinus, often occurs. To avoid these complications Freeman devised the following technic in suturing which will be described in connection with inguinal hernia. Three or four sutures, silk-gut, silver wire, or silk, are used, doubled, with both ends threaded through the eye of the needle. These are passed through Poupart's ligament and then through conjoined tendon as in Bassini's operation. There is now a series of loops along Poupart's ligament through which a rigid silver wire is passed. Along the conjoined tendon project the free ends of the sutures, between which another silver wire is passed and the sutures tied. This makes a series of quilled sutures. The upper ends of the wires are placed high enough to sufficiently close the internal ring, and the lower ends are bent so as to project out of the lower end of the wound. The suture ends are left long and are brought up out of the wound, which is then closed as in Bassini's operation. After ten to fourteen days there is fairly firm union and the wires are withdrawn through the lower end of the wound and the sutures are then easily withdrawn. After union has occurred sutures are of no utility, for if there is no tension they are superfluous, and if there is tension they cut the tissues. The method has the following advantages: It is simple and quickly done; considerable tension is easily overcome; the sutures cannot cut through; a large amount of muscle is closely and evenly applied to Poupart's ligament, favoring firm union and, therefore, permanent cure; the sutures are readily removed leaving nothing to irritate the tissues and cause sinus formation. The same method may be adapted to other forms of hernia.

Treatment of Pneumonia.—In the recent numbers of the *Practitioner* numerous interesting articles have been written by the best authorities of England on pneumonia, its various phases and treatment. In the March number J. Duschfeld has briefly reviewed the various modes of treatment of the past, and concludes that the routine use of such methods as venesection, large doses of tartar emetic, or digitalis have never reduced the mortality of the disease, and, since each individual case presents its own peculiar indications, no routine treatment should ever be adopted. He advises, so far as the general management and diet are concerned, that the patient should always be kept in bed, in a well-ventilated room (60° to 63° F.) and should wear light flannel garments. A daily bath in tepid water should be given and the mouth and tongue kept clean and moist. The food should be light, but abundant and nutritious. Milk (3 to 4 pints in twenty-four hours) mixed with lime-water, together with beef tea and broths are usually well borne. Too much liquid food should not be given, especially in alcoholic patients, on account of the danger of producing flatulence and tympanites which may cause cardiac dilatation, to which alcoholics are particularly prone. He usually gives from the onset quinine (two doses, 5 to 10 grains, in twenty-four hours), and the application of an ice-bag to the affected side, except in old people and those troubled with bronchitis. For the pleuritic pain, a mustard poultice, or, if severe, leeches give considerable relief. Morphine may safely be given in the early stages. The use of quinine, ice-bag and repeated cold sponging usually keeps the temperature down sufficiently, but the cold bath or ice-pack may be necessary. Antipyretic drugs are seldom used at the present time. The circulatory system requires the most careful attention. Except in plethoric subjects, the use of digitalis should be begun early. In old people, alcohol and carbonate of ammonia have better effects. The subcutaneous use of strychnine is often beneficial, and where deficient aeration exists the use of oxygen is advisable. For insomnia, morphine may be used at first, but when expectoration appears it may be a dangerous drug and chloralamid (10 to 20 grains) is more useful. Paraldehyde (2 to 3 drams), especially in alcoholics, is particularly efficacious. The noisy, active delirium is best treated by the cold-pack or bath combined, if necessary with the above hypnotics. The presence of albumin and casts in the urine is usually due to the high temperature and, therefore, re-

quires no treatment. If collapse occurs at the time of crisis, hot applications should be used and stimulants, such as alcohol and strychnine, subcutaneously.

Gangrene of the Lungs.—There are three varieties of this, the diffuse, the circumscribed, and the pleuropulmonary, and the last two, according to H. Vulliet of Lausanne (*Revue Méd.*, Feb. 20, 1900), are best treated by operation. Portions of one or more ribs are removed, the gangrenous cavity entered, and all pus-pockets broken up. Free drainage is established. If the pleura is not adherent the risk of the operation is increased, but the most serious complication is hemorrhage, which can be stopped only by firm packing. Following the operation the cough and expectoration may persist, but it is no longer fetid, is less purulent, and with internal medication slowly subsides. Success depends less on surgical ability than on an early and accurate diagnosis.

Progressive Muscular Atrophy.—The peroneal type of this disease is rare and the report of two cases by T. Diller (*Phila. Med. Jour.*, March 17, 1900) is of interest. The especial points of note in these cases were: The occurrences of the disease in two members of the same family; its slow, insidious onset in the leg muscles with the steady progress of palsy and atrophy, with later involvement of the thighs and then of the arms; the absence of knee-jerks; the age of onset, in both cases before twenty years; the absence of hypertrophy; the presence of quantitative and qualitative electrical changes in the wasted muscles and the absence of pain. The author contributes nothing to the pathology of this affection, as his patients have not come to autopsy. He believes, however, that the disease is of the myopathic type of atrophy in that it is due to an original embryologic defect and is a family affection.

Senile Cataract.—From time to time there are reports of the spontaneous disappearance of senile cataract. These reports have been fully substantiated and the foremost ophthalmologists now freely recognize the possibility of this sequence. W. L. Pyle (*Phila. Med. Jour.*, March 17, 1900) considers this subject in detail showing that the reported cases may be classified as: Cases in which there was absorption after spontaneous rupture of the anterior or posterior capsule; cases in which there was spontaneous dislocation of the cataractous lens; cases in which there were intracapsular resorption of the opaque cortex and sinking of the nucleus below the axis of vision, after regenerative changes in Morganian cataract, without rupture of the capsule or dislocation of the lens; cases in which there was complete spontaneous resorption of both nucleus and cortex without history of ruptured capsule, dislocation or degenerative changes of the Morganian type, and cases of spontaneous disappearance of incipient cataract without degenerative changes or marked difference in the refraction. He further reports illustrative cases of each class. With reference to the treatment of senile cataract he says that drugs have proven valueless, and, that, further than good hygienic modes of living, careful and repeated refraction, and the proper use of the eyes, nothing has yet been demonstrated to be of distinctive curative value.

Lesions in Brain Concussion.—An interesting post-mortem account of a severe fracture of the skull and its effects on the brain is given by G. Hauser (*Deutsch. Archiv f. klin Med.*, Bd. 65, Hft. 5 and 6). The fracture was due to a blow in the right temporal region and from there extended forward to the posterior part of the orbital roof anterior to the wings of the sphenoid, whilst below it reached the middle cerebral fossa. An examination of the brain showed the changes to be most marked in the right corpus striatum and left thalamus. The nodullary sheaths appeared segmented and degenerated and the axis cylinders swollen. No marked lesions could be found in the ganglion cells. Dilatation of the perivascular lymph-sheaths was present in the affected areas, but no hemorrhage. Over the cortex, opposite to where the blow was received, there was extensive meningeal hemorrhage but not at the site of injury. The peculiarities of this case consisted in the severe central changes without cortical involvement and in the absence of all signs of contusion in the meninges and cortex. The symptoms the case presented were briefly as follows: First, concussion signs with recovery after several hours. Paralysis of the left arm and tongue with incomplete paralysis of both legs soon followed. Cystitis with peritonitis and hyperpyrexia preceded death.

Fracture-Dislocation of Humerus.—B. F. Curtis (*Annals of Surgery*, March, 1900) says that fracture-dislocation of the upper end of the humerus requires very early operative interference, except in the few cases which can be reduced by manipulation. Operation consists in resection or reduction. The best functional result obtained after resection is not to be compared to the nearly perfect joint sometimes obtained by reduction. The result of reduction may be far from this perfection and yet be as good as the best result from resection. Resection is easier and leaves a more easily drained wound. For anterior displacements the incision parallel to the anterior border of the deltoid is best. Subglenoid and posterior displacements require posterior incision, preferably Kocher's. The head may be fastened to the shaft by either a wire or a pin. The great danger of the operation is infection, and a small drain is advisable where perfect asepsis has not been attained. It is very important to begin passive motion early, ten to fourteen days after operation, superintended by the surgeon. Voluntary motion is not allowed until consolidation is well advanced. Early motion prevents adhesions, and, more important yet, helps to prevent atrophy of the muscles, which is bound to occur to some extent, and partly explains the difficulty of obtaining good functional results when operation is done more than a

month after injury. After resection the patient may move the arm as freely as he chooses after the wound is healed.

Angina Pectoris.—Wm. Miller Ord (*The Polyclinic*, London, Jan., 1900) says that in attacks of this syndrome we are to consider degeneration of the heart-muscle, dilatation, hypertrophy, valvular disease, and arterial tension. There is a class of cases with feeble, ill-nourished heart, low tension pulse, and overirritability of the nervous system. In case of valvular disease, compensation may be temporarily upset by excitement or exertion, and may result in a characteristic attack of angina. Attacks are brought on also by moving about actively after a meal, by going from a warm room into a cold wind, by digestive disturbances, and by constipation. Glycosuria not infrequently accompanies the attack. With regard to treatment, have the patient avoid excitement or overexertion, take rest after meals, and keep the bowels open. Nitroglycerin or digitalis may be indicated; or, sometimes one-hundredth of a grain of nitroglycerin with five or ten drops of tincture of digitalis may be given, three times a day, for long periods with benefit. Anemic patients require iron.

Movable Kidney.—C. M. Moullin (*Brit. Med. Jour.*, March 10, 1900) says that during life the kidneys with undisturbed anatomical relations possess a range of movement of from 3 to 5 cm. Therefore, it is hard to define a movable kidney. The most satisfactory test is the failure of the kidney to reascend with the diaphragm on tranquil expiration when the patient is standing erect and has forced it down by deep inspiration. This is a sufficient test even although the kidney come only low enough for its lower end to be felt. On the other hand, when it follows up the diaphragm, it is not unduly movable even if half its surface is palpable. The kidneys are maintained in position by pressure of the abdominal viscera, and by the way they fit into the lumbar recesses which are pear-shaped with the small end downward. Neither of these two factors is sufficient alone. In women the lumbar recesses are more shallow and cylindrical, especially on the right side. When man assumed the erect posture, the lumbar recesses became shallower and broader, especially at the lower end; gravity increases the tendency to free mobility, and the other viscera being in front exercise their restrictive influence at a mechanical disadvantage. Movable kidney is certainly hereditary and common, more in women especially multiparæ, and more on the right side. For treatment one chooses between an abdominal belt, with massage and exercises, and nephrorrhaphy. The belt succeeds only in mild cases. Nephrorrhaphy never fails if properly executed.

Diffuse Infective Peritonitis.—Persistently fatal as are the majority of cases of this condition yet during the past five years prompt surgery has resulted in recovery in a number of instances. Chas. H. Goodrich (*Brooklyn Med. Jour.*, March, 1900) cites twenty-eight cases, of which sixteen were due to appendicitis with 5 recoveries, two due to pancreatitis with one recovery, and one to salpingitis, with recovery. The others were all fatal and were due to typhoid ulceration, ulcer of transverse colon, carcinoma of colon, intestinal obstruction, and hemorrhage into the peritoneal cavity. Two were post-operative. The types of diffuse peritonitis are: The acute septic, with scant serous exudate and many streptococci, very fatal and usually post-operative; the suppurative; and the fibrinoplastic, where the suppurative process is accompanied by a tendency to form adhesions. As to treatment, dry sponging or free irrigation with salt solution met with equal results. For drainage glass tubes are to be preferred, wicking works fairly well, gauze becomes clogged, and in two cases, fecal fistulæ followed the use of rubber tubes. In two of the successful cases no drainage was used and the foot of the bed was raised to an angle of 45°. The author advises that the intestines be handled as little as possible, manipulations to be made with instruments where suitable; and he questions whether the shock induced by mopping the serous coat does not counteract the benefits of the mopping.

Constipation in Infants.—A good means of combating the constipation of infants is to give a decoction made of prunes and two to three grams of the pods of senna or of senna combined with manna. M. Sevestre prescribes the following preparation:

℞ Boiling water ..... ʒvi
Manna in flakes ..... ʒi
Senna pods ..... ʒi
Powder of burnt coffee ..... ʒiiss.

M. Strain and administer during the day.—*Bull. gen. de Therapeutique*, 8 Feb., 1900.

For Acute Bronchitis.—For this most painful stage, with intense cough and no expectoration, when the ordinary remedies are often of little service in easing the patient, Edgeworth recommends caffeine in connection with alkalies. He gives twenty to thirty grains of citrate of acetate of potassium every three or four hours during the day, and five grains of caffeine on retiring at night. This overcomes the spasms of the bronchial muscles and facilitates expectoration.

Powdered Sulphur for Scabies.—Sherwell has found the following procedure both inexpensive and efficacious, especially when several members of a family are affected, as they can easily all be treated simultaneously, and the parasite be thoroughly routed. The patient takes a bath, soaps himself well, and is then rubbed over his entire body with washed sulphur (a teaspoonful is sufficient). He puts on a clean nightshirt and gets into bed with clean sheets; half a teaspoonful of flowers of sulphur is then thrown over him and the covers shaken a little to distribute the powder. This procedure is repeated every two or three days for a week or two, by which time a cure should be effected.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

THYROID MEDICATION AND OBESITY.

THAT medicine is not free from its fashions is continually evidenced in the reflections of its practice in medical literature. Every dog has his day, however, and the thyroid therapy of obesity, which is now having its noon-day of popularity, bids fair to call forth some dissenting voices. In a recent number of the *Prager med. Wochenschrift* (Feb. 8, 1900) A. Porges enters a protest against the use of this agent in the treatment of obesity, and gainsays the widespread belief that nothing but good can result from its administration. With reference to their susceptibility to thyroid extract there are two classes of patients. The patients of the first class are constitutionally rebellious to the drug and their body weight remains quite unaffected even after prolonged courses of treatment, so that for them at least the extract is useless. The patients who lend themselves more readily to this form of medication are individuals who present certain remote but still demonstrable affinities, both psychically and physically with those effected with myxedema. In these experience has shown that after from three to eight weeks' medication a drop in weight of from four to twenty pounds may be counted on. The advantages attendant on the simplicity of the treatment, however, which requires none of the elaborate dietetic and other restrictions imposed by the older methods, are usually rather more than counterbalanced by the annoying and often really distressing palpitation, restlessness, tremor and insomnia produced. But still more serious is a condition which experiments on animals and clinical observation have shown to be constant, *viz.*, a great increase in the nitrogen coefficient of the excreta, indicating a pathological breaking down of the body albumin. What renders this of still graver import is the fact that the morbid processes once under way do not cease on withdrawing the drug, but that there is always a possibility of their continuing for an indefinite period of time. As opposed to the older, safer, surer and always equally efficacious methods the author thinks that the uncertainties, discomforts and very possible dangers accompanying the use of the gland extract should exclude this field at least from the domain of organotherapy. In closing, he quotes the following conclusions of Epstein's:

(1) Obesity-cures with thyroid extract are practically unsatisfactory, because the attending weight loss is inconstant and under ordinary dosage frequently does not take place at all. (2) Obesity-cures conducted with this agent are not rational; as such can be considered only those which result in the obstruction from the body of fat alone. (3) Finally, the use of thyroid preparations in these cases is uncalled for, as there are enough other means at hand, if properly applied, to effect the desired result without any risks.

THE TOLERANCE OF BROMIDES IN ELDERLY EPILEPTICS.

NOTWITHSTANDING that we are beginning to lay less stress on the drug treatment of epilepsy, care in such methods is none the less important. Of all the sedatives used the bromides still hold first place. It is very unfortunate that so much mystery still cloaks the tolerance of bromides in epileptics. Some patients are able to take large doses, while others show evidences of intoxication on the slightest exhibition of the drug. The symptoms of poisoning are not influenced by age, as bromism in the aged is manifested by the same symptoms as in the adult. It is always dangerous to give very large doses of bromide at the onset in the treatment of epilepsy, although this danger can be met in great part by attending to intestinal antisepsis and cleanliness of the skin. To test the tolerance of the drug in any patient the bromides should be given without adjuvants,

as the latter not infrequently provoke intolerance. The maximum dose should always be determined by a slow, gradual increase of the drug. Individual tolerance varies extremely, especially in the aged, where bromide intoxication is apt to supervene because of organic changes in the heart and arteries. Intolerance of bromide may be shown by indigestion or vomiting, as well as by the usual skin and reflex symptoms.

Féré, in a study on the tolerance of bromides in guinea-pigs (*Revue de Méd.*, Jan. 10, 1900) found that after death the pigs still held more than thrice the daily dose of the bromide salt. He also demonstrated that some epileptics eliminated nearly the entire daily dose of bromide by the urine. Elimination was most active at the beginning of the treatment, an equilibration between the ingested and excreted bromides generally occurred in a period of two or three weeks. While, as a rule, aged epileptics show a diminished tolerance, the reverse is sometimes true, and in such cases Féré shows that the bromides may be administered with surprisingly good results. He presents many illustrative cases; one, man of 61 years, epileptic for twenty-six years, had not been given bromides the first four years of his hospital care, on the ground of the well-known intolerance to the drug in the aged, but as a final resort, when no other medicines could be found to influence the disease beneficially, the patient was placed on bromide. The commencing daily dose was 60 grains, increasing the first year to 150 grains; during the second to 225 grains, and the third year to 240 grains. The annual number of major attacks decreased in accordance with bromide medication in the adult. He passed from daily attacks to one attack in two months; at the expiration of three years' treatment the patient died of an intercurrent disease without manifesting bromide intoxication.

While giving bromides to the aged, particular attention must always be directed toward guarding carefully the threatened intoxication, as a relapse in the disease caused by an imperative suspension of bromide always necessitates a much larger dose of the drug on its resumption.

THE PATHOLOGICAL INSTITUTE OF THE NEW YORK STATE HOSPITALS AND THE MEDICAL SUPERINTENDENTS.

In our last issue we called attention to the threatened destruction of the Pathological Institute of the New York State Hospitals and asked for the responsibility of a movement against this plan of research, the most original and most fruitful that has ever been inaugurated in American psychiatry. It appears now, from the minutes of the last conference of the superintendents of the State Hospitals, that the men who should above all be eager and enthusiastic to hasten progress in our knowledge of abnormal mental phenomena, are the very ones who are ready to undo the advance work that the Director of the Institute has accomplished in bringing psychiatric research out of asylum restriction into the realm of general science.

We were under the impression that the necessity of scientific psychiatric research by the State was universally conceded when this Institute was first founded. Has the new Commission in its omniscience discovered that the benefits of scientific research are not wanted in the care of the insane? Is the President of this Commission the man to assume the responsibility of deciding whether or not the State shall be the patron of scientific work? Shall Dr. Wise dictate that researches in insanity are no part of the State function? This is a most important question. This is a matter for consideration of the medical and psychiatric profession at large as well as the general public, and not a question that Dr. Wise, Mr. Osborn or Dr. Cowles may arbitrarily settle by virtue of their power.

The sole function of the State in this connection is not to act as the simple custodian of the insane; there is implied in this authority the responsibility not only of doing its utmost to relieve the incapacitated, but to employ the material and the facilities, thereby afforded, of discovering the means whereby insanity can be prevented and the accumulating burden of the State relieved. There is something more in psychiatry, or at least there should be, than the grinding out of conventional laboratory data and the descriptions of lesions in individual cases. Such statistics and such data may be accumulated *ad infinitum*, but, without some generalizing principle to illuminate them, they remain only a mass of dead facts, an imperishable monument to industry, but of no vital importance. All hope of vitalizing this material lies in the Institute. That was the purpose of its organization, and is the purpose that must be steadily kept in view. If, in the judgment of those who are responsible for its existence and maintenance, its methods are not tending to that end, the methods should be changed. The Institute, however, as an instrument of scientific investigation should be preserved. Keep it free

from politics but hold it steadily to work along lines tending to the accomplishment of the ends whereto it was organized.

MOSQUITOES AS BEARERS OF MALARIAL INFECTION.

ALTHOUGH the evidence has been steadily accumulating that the responsibility for the infection of human beings with malaria rests upon the mosquito, further tests of this theory will be awaited with interest. The London School of Tropical Medicine is making arrangements to conduct some final and conclusive experiments in that paradise of malaria and mosquitoes—the Roman Campagna.

Under the direction of Dr. Patrick Manson a bungalow is being erected in the most malarious part of the Campagna; this will be thoroughly guarded and screened by mosquito curtains, and here from May to October next will reside two skilled observers with their servants. Every precaution will be taken to guard against the possibility of being bitten by a mosquito. It is confidently believed that the entire party will thus escape malarial infection. In addition to this negative testimony, laboratory-bred mosquitoes which are known to be free from malarial infection will be taken to Rome and allowed to suck the blood of patients suffering from a mild tertian form of malaria, and then taken back to London. After a sufficient time has elapsed for the parasite of malaria to develop in their bodies and reach their venom-glands, these mosquitoes will be allowed to bite several healthy individuals who have never been out of England, or had any opportunity of contracting malaria. If the mosquito theory of disease be correct, then most of the persons thus subjected to infection should develop the disease within ten days.

ECHOES AND NEWS.

NEW YORK.

Duryea Convalescent.—Walter Duryea, the patient at Roosevelt Hospital who has been suffering from fracture of a cervical vertebra, is steadily improving and gives substantial hope of complete recovery.

Obituary.—The New York Neurological Society records with sorrow the death of Dr. John Cargill Shaw, one of its members and its third president. As president of the society he was an indefatigable worker, and his untiring energy was of great service in the early days of its history.

Kent Mansion for a Hospital.—The old Kent mansion, at Second Avenue and Sixtieth Street, Brooklyn, has been selected as the site for the new Bay Ridge Hospital, Dispensary and Training School for Nurses.

Contagious Diseases.—For the week ending March 17, 1900: Measles, 729 cases and 18 deaths; diphtheria, 256 cases and 45 deaths; laryngeal diphtheria (croup), 17 cases and 14 deaths; scarlet fever, 193 cases and 15 deaths; smallpox, 7 cases; chicken-pox, 33 cases; tuberculosis, 230 cases and 188 deaths; typhoid fever, 19 cases and 9 deaths; cerebrospinal meningitis, 3 deaths. Totals, 1484 cases and 292 deaths.

United Hebrew Charities.—The reports for February of the various committees of the United Hebrew Charities show that during that month the total number of applications for aid received and dealt with reached 4209. Relief was refused for sufficient cause in 942 of these cases.

Improvements at Bellevue.—Architects have filed plans with the Building Commissioner for the improvement of the Marquand Pavilion of Bellevue Hospital. The changes include the construction of a new auxiliary operating-room and are to cost $5000.

Misplaced Charity.—A boy named Andrew McEnaney was placed in St. John's Home, Brooklyn, a charitable institution, by his guardian in April, 1899. Several weeks afterward the boy escaped from the Home and went to live with his brother. His guardian instituted legal proceedings to secure the custody of his ward so as to return him to the institution. It developed during the hearing in Court that the boy's guardian holds $10,000 in trust for him; he will, therefore, not be likely again to see the inside of an eleemosynary institution.

Medical Legislation.—Governor Roosevelt has signed a bill providing that the State Commissioner of Agriculture may quarantine a district in which rabies is present. The bill exempts from liability any person who may kill an animal so afflicted. A bill has passed the Legislature appropriating $10,000 per year for the slaughter of animals infected with tuberculosis. The Assembly has passed the bill providing for pure beer, ale and porter by limiting the legal ingredients to hops, malt, pure water and pure yeast. The Senate Judiciary Committee has reported favorably the bill giving the State Board of Charities power of visitation and inspection over the Society for the Prevention of Cruelty to Children. The bill regulating the working-hours of pharmacists and drug-clerks in New York City has been defeated in the Senate by a vote of 21 to 20.

PHILADELPHIA.

Jefferson and Princeton.—The report that Princeton University had made overtures for a

union with Jefferson Medical College has been denied by President Patton, who states that there is no immediate prospect for a medical school at Princeton. Dissection is prohibited in New Jersey.

Homeopathy.—The Philadelphia Post-Graduate School of Homeopathics has practically been absorbed by the Dunham College of Medicine of Chicago, the Dean, Dr. J. T. Kent, also going to the latter place. The question of organizing another school here is being considered.

Health Report.—Deaths in the city for the week ending March 17th were 580, an increase of 69 over those of last week and an increase of 60 over the corresponding week of last year. Contagious diseases: Diphtheria, 63 new cases, 22 deaths; scarlet fever, 50 cases, 3 deaths; typhoid fever, 106 cases, 17 deaths. Measles have been unusually virulent, 63 new cases and 26 deaths being reported. There were 7 deaths from influenza.

Anatomy of Hanging.—At a meeting of the County Medical Society, March 14th, Dr. Edmund W. Holmes stated that the majority of deaths from hanging were caused by apnea instead of dislocation or fracture of vertebræ. In experiments upon the cadaver only one fracture of the atlas occurred. The force of the drop is exerted in the line of the body on the under surface of the chin and occiput. Unconsciousness is caused by concussion of the brain due to the sudden impingement of great force at these points. Asphyxia and deaths follow, a fracture or dislocation of the cervical vertebræ being an accident.

Prize Essay.—No essay worthy of the Samuel D. Gross prize of $1000 having been received by January 1, 1900, the trustees will award the prize October 1, 1901. The conditions governing the prize are that it "shall be awarded every five years to the writer of the best original essay, not exceeding 150 printed pages, octavo in length, illustrative of some subject in surgical pathology or surgical practice, founded upon original investigations, the candidates for the prize to be American citizens." The trustees are Drs. W. W. Keen, J. Chalmers DaCosta, and J. Ewing Mears.

College of Physicians.—At the Section on Gynecology, March 15th, Dr. Barton Cooke Hirst reported the case of a woman who had introduced a piece of wood and a buttonhook into the uterus to cause abortion. She was operated upon five weeks afterward. The uterus and a knuckle of bowel had been perforated. These perforations were closed, the critical condition of the patient making a more radical operation impossible. The surrounding bowel looked healthy. A fecal fistula formed on the second day. Three weeks afterward, a curious slough was noticed when the wound was dressed. This was lifted out and found to consist of the caput coli and four inches of the ileum. The patient now passes feces naturally by the anus. She is comfortable and has gained twenty pounds in weight.

Dr. G. G. Davis reported a most remarkable case. The patient was a married woman of twenty-five. The menses gradually ceased during which time the patient's voice became harsh and hair grew on the face, breast and extremities, shaving of the face being necessary. The left side of the abdomen enlarged and in 1895 a large multilocular cyst of the left ovary was removed. The menses, which had been absent four years, reappeared thirty-one days after operation and the patient gained forty pounds in weight. Fifteen months afterward she became pregnant. During pregnancy her voice became less harsh and the hair fell out of the chest and abdomen and became much less marked on the face and extremities. Two lumps having appeared in the line of the incision, a second operation was performed in January, 1899. A large mass containing both liquid and solid contents was found attached to the posterior surface of the scar and projecting into the abdomen, being nourished by omental vessels. There was no recurrence at the site of the original cyst. Later a lump appeared to the left of the incision and large masses could be felt in the abdomen. The patient died in January 1, 1900. The growth last removed was papillomatous with probable carcinomatous degeneration. An interesting question is, What caused the growth in the scar of the first incision? Two explanations were suggested: That the wound was infected by the cyst contents at the time of operation, or that infection had taken place from contact of the tumor before removal.

CHICAGO.

Hospital for Consumptives.—The contributions for this hospital now amount to $16,376.

Free Medical Dispensary.—Under the auspices of the Englewood Bureau of Associated Charities, a free medical dispensary has been opened at 611 Sixty-third Street. The medical staff consists of Drs. Frank Billings, Weller Van Hook, W. E. Schroeder, Frank X. Walls, Frederick R. Green, Harry Kahn, and H. T. Tillotson.

Defense of Medical Inspection.—The attorneys of the Chicago Board of Education have filed an answer in the Superior Court to the petition for a mandamus, asked by Paul Wright, who asserted that his daughter, Mary, had been illegally prevented from reentering the Kershaw School by the operation of the medical inspection rule. The contention of Mr. Wright, that his daughter had the certificates of the family physician that she was without contagious disease, is answered by the attorneys with the statement that unreliable certificates from family physicians have become so frequent that the Board has been compelled to employ medical inspectors. The attorneys for the Board claim that as the result of the medical inspection in the public schools, there has been a decrease of contagious and infectious diseases since January of over 60 per cent. The officials

of the Board, intend, if necessary, to carry the case to the Supreme Court before abandoning the rule requiring medical inspection of pupils before they shall be permitted to reenter school.

Mortality Statistics.—According to the weekly bulletin of the City Health Department, during the week ended March 10th there were 526 deaths reported. Pneumonia was the chief cause of death, claiming 105 of the total mortality, this being 5 more than during the week preceding and 1 more than the corresponding period of a year ago. Of the total deaths 105 were among children under one year of age, and 112 were of persons over sixty years of age. During the week 12 fewer deaths from diphtheria were recorded as compared with the preceding week, but the mortality from this cause is still in excess of the corresponding period of 1899. The mortality from scarlet fever is steadily diminishing, the 5 deaths from this cause being the fewest reported for any one week during the year, and is less than during the corresponding period of a year ago.

Castor Oil in Neuralgia.—At a meeting of the Chicago Academy of Medicine, held March 9th, Dr. Harold N. Moyer read a paper on this subject in which he said that during the last two years he has treated about fifteen cases of neuralgia by this method, but only seven of these patients were sufficiently long under observation to enable one to speak definitely of the results of the treatment. Some years ago Dr. A. J. Ochsner called his attention to the value of castor oil in the treatment of neuralgia, particularly of the fifth nerve. Five of the cases were neuralgias of the facial nerve and two were typical cases of brachial neuralgia. Of the cases of brachial neuralgia, one had lasted one week and the other two weeks. The one of the shorter duration was exceedingly severe and had been under the care of a competent neurologist for more than a week. He was given a large dose of castor oil at one o'clock, and by four o'clock the pain had largely decreased in the arm; the following night he rested well and the next morning the pain had practically ceased. Three or four doses of the oil were taken afterward, and there was no return of the pain. An acute and recent case of neuralgia of the inferior dental nerve was cured in two weeks. Other forms of neuralgia were treated with the oil with satisfactory results. The oil is administered in the morning before breakfast and the dose is from one to two ounces.

Histopathology of Melanosarcoma of the Skin.—At a meeting of the Chicago Pathological Society, held March 12th, Dr. Alfred Schalek read a paper on this subject. Melanosarcoma of the skin was previously regarded as a connective tissue tumor, but this theory has been recently the subject of much controversy among pathologists since Unna first declared that it originates from the epithelium of the surface. Ribbert takes another view, claiming that a special pigment carrying connective tissue cell, the chromatophore, is the only possible matrix of pigmented moles and melanosarcoma arising from them. The histological examination of sections of several pigmented nevi and melanosarcoma of the skin show very nicely the gradual separation of pigmented epithelium from the rete; they become isolated and undergo a metablastic change and are surrounded by fibrillar connective tissue, form alveolar nests of new cells, and are particularly stellate and branched cells of the shape of chromatophores. The writer arrives at the same conclusion as Unna, that melanosarcoma of the skin is of epithelial origin and should be classed with carcinoma.

Nitse's Cystoscopy in the Female.—Dr. Gustav Kolischer, at a meeting of the Chicago Medical Society, held March 14th, read a paper on this subject. The principle of modern cystoscopy consists in unfolding the bladder by distending it to such an extent that its inner surface becomes visible, throwing light into the viscus either by means of reflected mirrors or by introducing an electric lamp into the cavity. The bladder is distended with air or water. The first method was introduced by Pawlik, and later on utilized by Kelly. For the second method the profession is indebted to Nitse. In performing Nitse's cystoscopy the bladder is filled with water through a catheter; general or local anesthesia is not required. Nitse's method is preferable to others as far as the comfort of the patient is concerned. From an experience extending over ten years, and a large amount of clinical material to work on, after having previously used Pawlik's cystoscopy, the author believes that cystoscopy as practised by Nitse is far superior to any other method in that it is exact and comparatively harmless.

GENERAL.

A Needle in the Appendix.—A sewing-needle, two and one-half inches long, was recently found in the vermiform appendix of a patient operated upon at Hartford, Conn., for appendicitis. The young woman remembers having swallowed a needle several years ago.

Studying Plague Quarantine.—The President of the Board of Health of Honolulu is visiting the various quarantine stations of the United States to study the methods of managing infected vessels and crews. It is said that he comes at the request of the Federal Government. In the practical management of a plague invasion he is doubtless able to return compliments, owing to his recent successful encounter with the disease at home.

The Price of Drugs.—Justice Russell of the Supreme Court, N. Y., has handed down a decision dismissing the complaint in the action brought by the John D. Park & Sons Co. against the National Wholesale Druggists' Association for an injunction restraining the defendant from refusing to sell patent medicines except on an agreement to maintain the rates set by the defendants at which the goods are to be retailed.

Smallpox in Paris.—Smallpox is considered to be increasing in Paris. Active steps are being taken to stamp it out. In view of the approaching opening of the Exposition the importance of this becomes apparent.

Divine Healer Arrested.—A "divine healer" has been arrested in Boston charged with using the mails for fraudulent purposes. His specialty is "absent treatment," and he had been so successful in duping people that he employed about a dozen female typewriters and copyists. It is encouraging to know that one of this pestilential gang is in the clutches of the law, with a prospect of being subjected to fine or imprisonment.

Christian Scientists Sued.—A man who was subjected by his family to Christian science treatment at Baltimore has brought suit against the readers of the First Church of Christian Science in that city, demanding $20,000 damages. He was under treatment by the "reader" of this church for more than three months, during which time he steadily failed, but was finally restored to health by a regular physician, who was fortunately called in.

The Antituberculosis Congress.—Under the patronage of Her Majesty the Queen of Italy, the Congress for combating tuberculosis wiss assemble at Naples, April 25 to 28, 1900. Physicians, naturalists, and engineers, as well as representatives of social and philanthropic sciences, are entitled to take part. The Congress will be divided in four sections, each having a separate committee of arrangements, as follows: (1) Etiology and prophylaxis; (2) clinical pathology; (3) therapeutics; (4) sanatoria. His Excellency the Minister Vavelli is president of the Congress and Professor Enrico de Renzi is chairman of the general committee of arrangements.

The Future.—Health Officer Seys, in his annual report to the Board of Public Affairs of Springfield, Ohio, states that last year only 718 children were born in that city, which has a population of 45,000. Of this number of births 216 were the children of the 1075 Catholic families, so that there were born to the remaining 39,625 inhabitants only 502 children. Instead of 718 children there should have been 1808, if the births had been equally divided among all classes. "Such conditions," observes the doctor, truly enough, "result in the downfall of all nations."

Contagious Pneumonia.—On March 8th John Swarts of Deckerstown, New Jersey, died of pneumonia. He was ninety years old. Two hours after his funeral his daughter, aged sixty-five, died of the same disease. Another daughter lay in an adjoining room seriously ill with pneumonia, and she died on March 16th. A married daughter came to nurse her father and sister, and she became ill with pneumonia and had, on March 16th, but slight chance of recovery. A son and his wife have since been afflicted with the same malady. The community has become alarmed at the evidently contagious nature of the pneumonia and will not help the sick people.

A Bad Case of Indigestion.—Arthur Shult, a dime museum freak who has posed as the "Human Ostrich," and whose specialty was the apparent eating of glass, old iron, nails, chains, etc., had to undergo gastrotomy at Johns Hopkins Hospital on March 17th. His method was to deceive his audience by adroitly palming the indigestible objects he was supposed to swallow. His reputation spread so that a class of medical students arranged for a private exhibition and frustrated his attempts to palm by compelling him to remove his coat, without the sleeves of which he was helpless. He then deliberately swallowed the junk he had intended to palm. He soon became ill and was operated on by Dr. Halsted.

Obituary.—Dr. Samuel Hayes Pennington, Princeton's oldest graduate, died at his home in Newark, New Jersey, on March 13th. He was ninety-four years old. Until about three years ago he was accustomed to take long walks and his step seemed as firm and brisk as that of a young man. He was graduated from Princeton in 1825. After leaving Princeton he attended lectures under the Rutger's Medical Faculty of Geneva College, and he received the degree of M.D., 1829. For seventeen years he was a member of the Newark Board of Education. He was a member of the Princeton University Board of Trustees and President of the Newark City National Bank. He was corresponding member of the Medical Society of Munich and of the Royal Botanical Society of Ratisbon. Princeton conferred on him the degree of LL.D. in 1835.—Dr. Thomas B. Hood, a prominent physician of Washington, D. C., died in that city on March 15th, at the age of seventy-one. He served as a surgeon in the Civil War. Subsequently for eleven years he was medical referee of the Pension Office. He had been a professor in the Harvard Medical School and was identified with many charitable institutions.

The Plague.—The Plague is reported to be still raging on the Island of Mauritius, the weekly death-rate averaging from 50 to 75 victims. Since the outbreak of the plague, January 25, 1899, between three and four thousand people have been attacked and 80 per cent. of these unfortunates have succumbed to the disease. The President of the Superior Board of Health of Mexico reports to the United States Marine Hospital Service that after thorough and careful investigation he is able to state that no case of bubonic plague has occurred on the Island of Cozumel, off the coast of Yucatan.

A new rat-proof quarantine wharf has been constructed in the Honolulu harbor. It is built on copper-sheathed piling, is well isolated, and entirely surrounded by water. The total number of cases of plague that have occurred in Honolulu from the outbreak of the epidemic to February 21st, at which time it was exterminated, is

62, of which 53 died and 9 recovered. The Health Board of Oregon has addressed a communication to the citizens of Astoria, in that State, urging upon them the necessity of poisoning all rats about their homes as soon as possible as a precaution against the spread of the plague in case of its appearance there.

This is now the fourth successive season that plague has appeared in Bombay, and every outbreak has proved more serious than its predecessor. The number of deaths from all causes has steadily risen during the past six weeks. In Calcutta the plague retains its grip and is rapidly becoming epidemic. At Hong Kong during the first week in February a slight recrudescence of the disease occurred, 7 cases being reported on the first of the month and 8 on the second. Japan seems to be entirely free of the plague, and so is the entire continent of Europe. The success in stamping out the disease in Oporto is a most encouraging demonstration of the fact that it is possible to eradicate it, even if it seems to have obtained a substantial foothold.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, March 12, 1900.

SITE OF IMPERIAL YEOMANRY HOSPITAL—ARE AMBULANCES AND SURGEONS REALLY NON-COMBATANTS?—THE LONDON SCHOOL BOARD'S WATCHFUL EYE—NEW TAX ON EYE-HOSPITALS BY SCHOOL BOARD—DENTISTS FOR THE SCHOOLS—SCHOOLS AS A FACTORY FOR SOLDIERS—ANOTHER MALARIAL EXPEDITION—THE HOUSING-BILL — "LEGITIMATE ADVERTISING" — SCURVY AND POLAR EXPLORATION.

The site of the Imperial Yeomanry Hospital has finally been decided upon, in a bordering region of the high veldt, about twenty miles from De Aar, on the roal to Kimberley. This is in a "sanatorium" region, according to all the authorities on African climate, and the winter climate is delightful, although the appearance of the country about is hardly attractive. To have a large, well-equipped hospital like this close to the seat of war will be a great advantage in every way and save many a poor fellow the long and wearisome journey to Cape Town.

The war-correspondent of one of the London medical journals has struck out an idea upon the protection accorded to ambulances on the field of battle which has, at least, the merit of originality. He declares that it is "absurd" to regard them as entirely non-combatant, since their chief function is the relief of the slightly-wounded with a view of getting them ready to fight again as quickly as possible! There is truth in the suggestion, but we fear the principle asserted would involve rather too much if generally accepted. What of the officers and men of the Medical Corps and the immunity from intentional attack extended to them? For since the full adoption of asepsis two-thirds of their activities are unquestionably directed toward this same result. Their function now is not merely the relief of suffering and cure of the wounded, but the rapid repair of the human units of the great fighting machine. As a matter of fact, their activities add enormously to the actual fighting strength of any given army in a campaign. But are they on this account to be regarded as practical combatants? It is a nice question, but one that will be swiftly answered. The moment your enemy is disabled he becomes sacred from further attack and every agency which can relieve his suffering or save his life comes under the same egis, no matter what use he may be certain to make of his restored health in the future. Abandon this in any degree and warfare ceases to be civilized.

The London School Board is still keeping a watchful and intelligent eye upon the physical basis of education. Its Committee has just reported again upon the advisability of supplying free meals for underfed school-children, recommending that a special subcommittee be appointed to take the matter in charge and arrange for any needs of this sort being promptly met.

Another result of its solicitude about physical fitness is not so fortunate. A number of children whose eye-sight had been found defective, presumably by the teachers, were calmly given cards instructing them to have their vision examined at one of a list of hospitals appended. The result was that one fine morning several of these hospitals were suddenly overwhelmed with refraction-cases. No notice had been given to the hospitals or any attempt made to confine the cards to children whose parents were unable to pay for a private examination, and the staff, not unnaturally, objected vigorously. Now the Central Hospital Council for London has taken the matter up and addressed a formal protest to the Board against their inconsiderate action and very pertinently suggesting that they should appoint qualified ophthalmic surgeons in each school area to have general care of the eye-sight of the children, as is already done in Germany. At the same time the Council advises the hospitals to refuse to examine more than a certain limited number of such children per diem and to weed out all whose parents are not really entitled to hospital-service. What made the inrush of children more provoking was the fact that many of them were found to have perfectly normal vision and accommodation, so that the eye-tests must have been made under the influence of some craze for "physical measurements" by the teachers themselves.

A novel suggestion as to the physical side of education has just been made in Parliament. A member asked that, in view of the bad condition of the teeth of so many of the recruits who present themselves, the Council on Education shall appoint qualified dentists, who shall go to the schools at regular intervals, examine the teeth of

all lads over ten years of age and advise them as to the best measure of preserving them. The Committee of Council, of course, simply promised in chill official accents to "consider" the suggestion. While it would be an admirable thing in every way, especially if extended to the girls as well, we doubt whether the most enthusiastic physical educationalist would approve of turning the schools into a manufactory for soldiers in quite such a barefaced fashion.

The plucky little Liverpool School of Tropical Medicine is to the fore again with another malaria expedition. This will proceed to the West Coast of Africa and go up the River Niger to Old Calabar for the special purpose of working out further problems in the dissemination of malaria by *Anopheles* and its prevention. It is expected to start about the end of March.

The new Government amendments to the Housing-Bill are condemned on all hands as mere "tinkering." Sanitarians and reformers of all shades of political and racial opinion unite in expressing their disappointment. Almost the only step in advance of any value is the granting of power to municipal bodies to purchase or lease land for building purposes outside of their own areas and thus relieve their internal congestion. A number of amendments will be presented in the House, especially with regard to holding the owners of slums and rookeries responsible, in part at least, for the condition of their property and for the expense of its destruction and clearance. As one reformer pertinently remarks: "We do not compensate the owners of bad meat or decaying fruit, why should we those of rotten houses?" At present rates the cost of clearance of slums is something enormous and an intolerable injustice to the community.

English medical journalism is becoming alarmingly progressive. The latest arrival in the London arena, the enterprising and interesting *Physician and Surgeon*, has already in its fourth number reached the point of formally discussing "Legitimate Advertising" by the profession and gives sage advice as to how the young practitioner may get the best results from his church affiliations, his political activities, and his interest in the various reform movements—nay, even favors the use of a carriage, however few patients he may have. He is even advised to call on the neighboring chemists and deal with as many tradesmen as his limited household expenditures will admit. Really, when your Englishman does get to thinking out loud, he is astonishingly frank! The *Physician and Surgeon* practises what it preaches, as it is for sale at all newsstands and announces its bill of contents every week upon a gaily-illustrated poster with huge headlines, upon the bill-boards at the railway-stations. The proper British profession is shocked—but it buys the journal.

A most interesting contribution to our knowledge of the causation of scurvy was made before the Royal Society this week in the papers of Mr. F. G. Jackson, the Arctic explorer, and Professor Vaughan Hurley, the well-known physiological chemist of University College. Both the papers were united in regarding the disease as due to ptomaines contained in badly preserved foodstuffs, rather than to deficiency of certain salts and elements in such foods, as the older view was. Mr. Jackson was able to report, as convincing proof of the correctness of the views of the writers, that, having planned the provisioning of his expedition upon the lines of the theory, not a single case of scurvy had occurred during their long stay in the Polar regions.

PROGNOSIS OF GLYCOSURIA AND DIABETES—MARRIAGE OF DIABETIC PERSONS—NEPHRITIS IN CHILDREN WITHOUT ALBUMIN—THE GERM OF WHOOPING-COUGH—ENTEROPTOSIS.

Hirschfeld read a paper on the prognosis of glycosuria and diabetes at the Berlin Medical Society, January 31st, in which he claimed that in even severe forms of diabetes recovery is possible. Strict withholding of carbohydrates from the food is not desirable on account of the danger of coma. A patient should be allowed two or three ounces of carbohydrates daily, or even as much as six ounces when improvement is well established. If the disease has existed a long time, or if acetone appears in the urine, the prognosis is much less favorable. Other unfavorable symptoms are attacks of painful colic associated with dysentery. The general appearance of the patient is not a safe guide to a correct prognosis. Often an increase in weight is accompanied by an increase in the excretion of sugar.

G. Klemperer said that there is a commonly accepted rule that diabetes is very dangerous in youth and much less so in old age. It had been his experience to meet many exceptions to this rule. For example, sugar was first noticed in the urine of a girl aged thirteen years. There was an unusually marked hereditary taint in this case; nevertheless after excreting for several years urine containing from one to two per cent. of sugar, the patient entirely recovered. Such instances are doubtless merely exceptions to the general rule that diabetes is grave in youth. The commonly quoted assertion that the longer a diabetes exists the less dangerous it is, is denied by Klemperer. The opposite is rather to be affirmed, for the longer the glycosuria exists, the more imperfect will be the assimilation of carbohydrates.

Senator spoke of the duty of the physician to advise against the marriage of every diabetic patient; not because of a possible bad effect on the patient, but because of the probability that a tendency to diabetes will be transmitted to the offspring.

At the meeting of February 7th Cassel discussed the subject of nephritis without albuminuria as occurring in young children, citing several instances in which the more or less abundant

urine was very pale, slightly acid, and of very low specific gravity. Although no albumin could be shown by any of the recognized tests, and neither were formed elements present, anasarca was marked. These and other symptoms led Cassel to the conclusion that there were cases of nephritis without albumin and casts, rather than cases of idiopathic anasarca. In two instances the children died and the microscopic examination of the kidneys showed parenchymatous changes to a greater or less degree.

Israel mentioned cases of nephritis without albuminuria occurring in adults. In one striking instance in which the diagnosis was verified by a microscopical examination of the kidneys, up to the time of the patient's death repeated examination of his urine failed to show the presence of either casts or albumin.

Arnheim described his efforts to isolate the germ of whooping-cough, at the meeting of February 14th. In two years he examined, bacteriologically, thirty-three patients suffering from whooping-cough, and made three autopsies upon subjects dying from this disease. He found almost constantly little staff-like bacteria, which were exceptionally formed in the tissue cells. These bacilli appeared identical with those described by Schablewski-Hensel, but they differed somewhat in form and method of growth from the microorganism which Ritter described some years previous.

At the Imperio-Royal Society of Physicians of Vienna, February 9th, C. Herzfeld spoke of enteroptosis, which he defined as an altered position of the abdominal organs, found usually in the female and occurring with great frequency. Its principal symptom is a disturbance of digestion. If the trouble comes from the stomach there will be loss of appetite, a constant feeling of hunger, pain on taking food, eructations, etc. If the intestinal digestion suffers there will be obstipation and diarrhea, gas formation, distention, and a feeling of fulness. Other symptoms of enteroptosis are pain, loss of muscular power, dyspnea, cardiac palpitation, headache, dizziness, and numerous nervous symptoms. Glenmore assumed that the starting-point of the trouble is usually a loosening of the support of the hepatic flexure of the colon. This allows the colon transversum and ascendens to sink, and they drag with them the other organs. This is not the case, for the chief force which keeps the various organs in place is the intra-abdominal pressure exerted from above by the thorax and weight of liver. This is met by the force of the intestines, which varies according to their contents, amount of gas, and so forth. An increase of pressure from above, as due to tight-lacing, or a reduction of the pressure from below. These changes lead to a displacement of the abdominal organs. In the large majority these follow pregnancy and childbirth, but they may follow equally well any sudden emptying of the abdomen, or diseases which reduce the tone of the muscles may bring about enteroptosis. The aim of treatment is to restore the normal pressure by means of bandages, which must exactly fit and should be put on while the patient is lying down.

If the floor of the pelvis is weak it should be strengthened by a perineal operation or by a pessory. As a prophylactic measure, close-fitting abdominal bandages should be worn.

SOCIETY PROCEEDINGS.

THE NEW YORK COUNTY MEDICAL SOCIETY.

Stated Meeting, Held Monday, February 26, 1900.

The President, George B. Fowler, M.D., in the Chair.

The subject of the evening was the discussion of the physiology and therapeutic uses of the suprarenal capsule.

Suprarenal Physiology.—Dr. B. Moore, Professor of Physiology in the Medical College of Yale University, discussed the physiological properties of the suprarenal capsules. He said: Our knowledge of the physiology of the suprarenal comes from three sources. First, from clinical medicine and the pathologic anatomy of these glands with the symptoms due to changes in them. This was the method that first brought the suprarenals into notice. Dr. Addison, in 1851, showed that their degeneration was associated with nervous and muscular asthenia and very greatly lowered blood-pressure. The second source was by the removal of these suprarenal glands from animals. Brown-Séquard, in 1855, showed that the removal of one of these glands from a guinea-pig was often fatal and the removal of both was always fatal. Later observers, however, have denied this. Schaefer suggested that in these cases of survival, accessory glands remained, and they are not rarely found at dissections, which make up for the organs that were removed. The third source of our knowledge of the physiological properties of suprarenal is the one that is now of special interest. It is due to injections of the gland and the observation of the results it brings about. The ingestion of suprarenal by the mouth causes no marked symptoms. Subcutaneously administered the results are neither very striking nor uniform. Intravenously the suprarenal extracts produce marvelous effects. A fraction of a milligram causes a rise of blood-pressure to double or treble what it was before. This is all the more striking as blood-pressure is usually very stable and is affected by very few drugs. The increase of blood-pressure arouses the vagus and this acts as a safety-valve in the prevention of overstimulation of the heart. As a consequence, when large doses are administered, the ventricle stops beating, just as if the vagus were directly stimulated, although the auricles continue beating. If atropine is used to paralyze the vagus before the administration of suprarenal then the heart stimulation is noted. It might be thought that suprarenal substance causes a rise in blood-

pressure by action upon the vasomotor system and constriction of the small blood-vessels. It is, however, a stimulant to all muscle fiber. All the nerves leading to a part may be cut yet constriction will take place when suprarenal extract is administered. If a freshly excised vessel of a diameter of ten to twelve millimeters be acted upon by some fluid containing suprarenal substance, the diameter at once goes down to one or two millimeters. The vessel practically becomes obliterated. This action has been seen very well in the inflamed conjunctiva.

Suprarenal Chemistry.—Extract of suprarenal is not affected by acids. The active principle retains all its energy even in a solution of ten per cent. of mineral acid. Alkalies destroy it at once. At one time the active principle was thought to be a reduction derivative of pyridin acting like nicotine or conine, which are reduction derivatives of pyridin. These substances resemble suprarenal extract so much that it is surprising they have not been used more therapeutically. If suprarenal substance be heated with dilute acetic acid and then with zinc acetate the material obtained is most active. One-millionth of a gram to the kilogram weight of animal will produce an easily perceived effect. Curiously enough a much smaller dose produces an exactly opposite effect, that is to say, it lowers blood-pressure. This happens with a good many drugs, however, and might have been more or less expected.

The subject of the significance of the glands during life is still a matter of unsettled theory. Animals are usually killed by the shock of the removal of both glands. It is an extremely delicate operation, almost inevitably involving important abdominal nerve-plexuses and so readily leading to a fatal termination from surgical shock. Of late, attempts have been made by infection of the glands with various bacilli to produce gradual degeneration. One operator has had reported success in this way and the procedure was followed by the development of the symptoms of Addison's disease. As to the mode in which the suprarenal affects the system, there are two principal theories. Schaefer thinks that there is some substance secreted by the gland which keeps up muscular tonicity. Not only the muscular tonicity of the blood-vessel walls, but also that of the whole muscular system. The French school advances the theory that in the course of body metabolism certain substances are produced which lower muscular tone and that the secretion of the suprarenals neutralizes these substances. They urge the fact that the blood of animals from which the suprarenal glands have been removed is toxic for other animals. This argument, however, loses some of its weight when we recall that the injection of blood from any animal whose nutrition is very much lowered may seriously affect a healthy animal.

Preservation of Suprarenal Solutions.—Dr. Lucien Howe, Professor of Ophthalmology at the University of Buffalo, sent a paper on this subject, which was read by the Secretary. The method employed for over a year now in Buffalo with excellent satisfaction is as follows: One-half a gram of the extract of suprarenal capsule is rubbed to a paste, then water is added gradually until there is a solution of one ounce. This is then heated for some time to 160° F. Water being constantly added as the solution evaporates so as to keep the amount of liquid always up to one ounce. Fifteen grains of boric acid are then added and the solution is ready. It will keep for weeks. The suprarenal extract is used in the eye in the shape of small wafers. To make these the extract is rubbed up into a paste and then mucilage added to give it consistency. These feel somewhat rough but are unirritating when moistened. The addition of formalin, 1-10,000 or the employment of a concentrated extract in glycerin diluted as required are good methods for preserving the substance. But both the formalin and the glycerin have proved irritating to some eyes.

Suprarenal Therapy.—Dr. W. H. Bates then read a paper, which see p. 441.

Suprarenal Extract for Nose and Throat.—Dr. H. L. Swain, Professor of Otology and Laryngology in the Medical College of Yale University, said: The first use of suprarenal extract in disease of the nose is to open up an occluded nostril. It acts promptly on the muscular fibers of the erectile tissue of the nose and it is wonderful how soon after its application a completely shut up nostril is free for respiratory purposes. It does not affect infiltration and it has no effect where there is no muscular tissue. When administered in conjunction with cocaine it produces the greatest possible contraction. No unpleasant symptoms follow its administration and it should be used freely. No intoxication or constitutional symptoms such as occur with cocaine follow it, and no habit develops from its use. In acute rhinitis the suprarenal lessens the congestion and consequently the secretion. Unlike cocaine, the membranes do not become accustomed to it and it can be used any number of times. Owing to its effect on secretions from the nose, it would seem to be the ideal remedy for hay-fever. Others have found that even when employed internally it acted very favorably on the disease. Such has not been our experience at Yale. When applied locally, however, we have found it extremely beneficial. After the application, oil of eucalyptus may be inhaled several times a day and especially just after the application. The asthmatic attack which occurs so often in connection with hay-fever as the result of pressure within the nose is promptly relieved. In these cases nitroglycerin, used in conjunction, seems to be of advantage. As a hemostatic in surgery of the nose, suprarenal extract is an extremely useful drug. Every specialist knows how much time is lost after operations on the nose while waiting for the bleeding to stop. If a solution of suprarenal extract is applied before and

after the application of the cocaine in these cases there is absolutely no bleeding. There are those who say that secondary hemorrhage occurs more frequently after the application of suprarenal extract for nasal operations than where it is not employed. Such has not been Dr. Swain's experience. The extract does not close up the varicose veins which sometimes exist upon the septum of the nose, but that seems to be because there is not enough tissue in the overstretched walls of the vessels to react to its influence.

Tonsillitis.—Suprarenal extract is an extremely useful remedy in tonsillitis. It gives great relief in all forms of the trouble. Patients speak of the immediate increase of space in their throats. Quinsy patients who have been suffering severe pain get some relief at once and are able to take the nutrition which they have had to deny themselves for days. When applied to the third and fourth tonsil it has a wonderful constringent effect which greatly relieves respiratory symptoms. The hypertrophied third tonsil can be removed bloodlessly under its influence. Acute edema of the glottis, especially in its early stages, is very favorably affected by the spray or by the local application of suprarenal extract.

Suprarenal Extract in Asthma.—Dr. S. Solis Cohen of Philadelphia said that asthma is not a nosological entity, but is associated with a great many different conditions due to very various causes. It is usually considered to be a paroxysmal disease without any gross, morbid pathology, although it may be associated with organic lesions of the most varied description and is especially prone to occur in renal and cardiac troubles. Simple asthma, without lesions or with but functional lesions, by which is meant pathologic alterations that have not as yet been detected even with the most refined methods, is due very probably to bronchial spasm. Occasionally it is due to spasm of the blood-vessels of the lungs, although in this case it is the pulmonary rather than the bronchial circulation that is affected. At times bronchial asthma is undoubtedly due to turgescence of the mucous membrane of the bronchi. It occurs, then, especially in highly neurotic individuals and is often associated with hay-fever. At times there is in these cases an alternating or continuous albuminuria. The extract of adrenals is not good for all cases of asthma, but will be found to benefit those patients who suffer from vasomotor disturbances, patients such as urticaria, fictitious urticaria, or dermography. Hay-fever patients who suffer from various neuroses who are very sensitive to changes in the weather and have capricious digestive disturbances or occasional cyclical albuminuria are especially benefited by the administration of the adrenal extract. It does not cut short paroxysms that have been once begun, but it mitigates their severity and lengthens the interval between them. The fear of the recurrence of paroxysms which haunts such patients and makes life so miserable is greatly lessened. The crucial test as to whether a patient is liable to be benefited is found in the fact that such are rendered worse by the inhalation of nitrite of amyl.

Suprarenal Extract in Hay-Fever.—Dr. H. Beaman Douglas said the discovery of the century is undoubtedly the use of suprarenal extract for this condition. In the perennial sneezing catarrh, with white, swollen turbinated bones, it is a most useful remedy. It will abort ordinary acute catarrh. Used internally it has a marked effect in lessening the symptoms of hay-fever and gives marked relief to the patient in twenty-four to forty-eight hours. Where five grains are given every hour distinct local effects are soon noticed. The nose is soon restored as a breathing organ, there are no dangerous sequelæ, no toxic symptoms to be feared and no liability to the formation of a dangerous habit. In certain patients some vertigo is noticed, the heart becomes a little more rapid than usual, and there is some nervous excitement, but nothing that need cause any worry. The only dangers of the remedy are theoretic and are not seen in practice. There is but one possible inconvenience that can be foreseen, and that is if the drug should be used constantly and persistently, the lessening of the blood-supply to the nasal tissues may lead to atrophy. The extract will abort asthmatic tendencies and will frequently arrest asthmatic attacks, although it will not affect asthma when the affection is fully developed; where, as is often the case, the asthma is due to congestion of the nasal passages, it will surely be benefited. Asthma on a gouty or rheumatic basis will also be benefited. When the asthmatic attacks are associated with an atheromatous condition, or are caused by interstitial nephritis, they will not be benefited. As a rule neurasthenic and neurotic patients in whom asthma develops are most helped. The extract may be applied on pledgets of cotton or by the spray every two hours until relief comes. The application or spray may be repeated whenever the symptoms return.

Suprarenal Extract in Laryngitis.—Dr. H. Holbrook Curtis said that in all forms of laryngitis suprarenal extract relieves the congestion, lessens the swelling and diminishes the pain. In addition to the spray a swab saturated with suprarenal solution should be used in the pyriform sinuses. In the laryngitis of singers, where the affection is not severe but yet is sufficient to prevent them from singing in public, an application of suprarenal extract in this way, five to ten minutes before a performance, will entirely restore them their voice and tone. The insufflation of the powdered extract gives the greatest relief to the dysphagia which is so prominent a feature of the disease. For relaxed vocal cords there is no remedy equal to the suprarenal extract. It acts not only to relieve any congestion in the neighborhood of the cords, but by a direct tonic action upon the muscles it tones the whole larynx. A marked feature of its use is that it is of equal service in congested as well as relaxed conditions.

Suprarenal Extract in the Urethra.—Dr. J. A. Moore has used suprarenal extract more than two hundred times in the urethra. He has found

that instrumentation can be accomplished without any bleeding and with the production of very little irritation under its use. A ten-per-cent. unfiltered solution injected into the urethra completely relieves its irritability. When a stricture is to be stretched it lessens the congestion, increases the caliber of the urethra, and prevents all bleeding. As its effect passes off quickly, if more than two sounds are to be used at one sitting, a second injection of the suprarenal extract should be made. No danger is to be feared from constitutional symptoms or from the local action on the urethra of any amount of the drug. In six meatotomies, Dr. Moore has used a twelve-per-cent. solution injected hypodermically and has had very little bleeding after the operation. When slight bleeding occurred it was at once controlled by dropping some of the suprarenal solution on the bleeding vessels. In gonorrhea the injection of suprarenal extract in two cases gave complete relief from the smarting, burning pain of urination during the acute stage of the disease. For chronic gonorrheal patches in the deep urethra, it may be applied as a paste through the endoscope and gives good results. In gleet, suprarenal given every two hours is the best cure for the morning drop.

In the discussion Dr. Vansant of Philadelphia said that for the granular condition of the vault of the pharynx, which so often occurs with the wide nostrils of atrophic conditions in the nose, suprarenal extract gives excellent results. In hay-fever the internal administration of the drug does good, but its local use is more advantageous. Solutions of the suprarenal are very prone to decomposition. Great care should be taken, then, to avoid contamination and to prevent the development of septic material not only before but after its application. The suprarenal solution should not be used as a spray, but should be applied on cotton swabs in order to avoid all danger of affecting the accessory sinuses of the nose. Secondary hemorrhages after nasal operations need not be feared if another astringent, for example, a weak solution of a silver salt, is applied.

Dr. R. H. Cunningham said that he does not share the enthusiasm for the suprarenal capsule that seems to be felt by so many. He has seen at least one case where both glands were completely removed from a dog and after two years the dog is still alive, seemingly without any bad effects. He has seen a bucketful of the extract given to dogs by the stomach without any effect. Such diseases as hay-fever and asthma would be benefited by any animal extracts if the suggestion were given that a new and powerful remedy was being used which was sure to do them good. A word of warning seems necessary with regard to the use of solutions of suprarenal extract in the eye. The extract is prepared in large slaughter-houses where aseptic conditions are impossible, and during the process of desiccation virulent germs may easily retain their vitality. There is danger then of setting up severe septic conditions in so delicate an organ as the eye.

Dr. Myles said that the effect of suprarenal extract in the nose is almost marvelous. In ten to thirty seconds the blood is forced out of congested tissues in the nose and they are made almost white. Operations on the nose may be conducted practically bloodlessly, even in people who have almost the bleeder's diathesis. Serious operations that made the nose specialist hesitate before the introduction of suprarenal extract may be performed with the flow of scarcely enough blood to moisten the upper lip.

Dr. Phillips said that suprarenal extract is of wonderful assistance in intratympanic operations and in operations in the attic. In these cases the bleeding is usually free and greatly obscures the site of operation. If a few drops of suprarenal solution are instilled before the ether is given and then a pledget of cotton soaked in this solution inserted in the ear when the time for operation comes, the tissues will be properly prepared. The operation will be practically bloodless. The field of operation will remain unobscured by blood and there will be less danger of injuring the facial nerve.

Dr. Hopkins said that there was more danger of secondary hemorrhage after nasal operations when suprarenal extract is used than when it is not. Patients are often at home when the hemorrhage begins and it is very disquieting. It is well, then, always to pack with gauze containing a mild styptic before the patients leave the office. When suprarenal extract is used in conjunction with cocaine there is less prostration from the drug and less tendency to toxic symptoms, because the constriction of the blood-vessels by the suprarenal extract prevents the absorption of cocaine to any serious extent.

NEW YORK ACADEMY OF MEDICINE—SECTION ON SURGERY.

Stated Meeting, held Monday, February 12, 1900.

Charles N. Dowd, M.D., in the Chair.

Complicated Elbow Injury.—Dr. Forbes Hawkes presented a case in which there had been a dislocation of the elbow and fracture of the lower end of the humerus. The patient, a boy of twelve, came to the dispensary after the injury had healed in order to see if something could not be done for the resulting deformity. He was found to have excellent use of the joint, flexion and extension were almost as complete as in the normal joint. It was his left arm and he was right-handed; he had as much power in the arm for all movements as most right-handed boys. Roentgen radiograms seem to show that the fracture in the case was a chipping off of the whole outer condyle of the humerus with part of the inner condyle. A false joint had been formed at the fracture and it was this that gave the good result in the case. The normal joint seems to be anchylozed to a greater or less degree as the result of the healing of the

injury which had taken place. The boy was advised not to have the arm operated on as it is doubtful if as good a result could be secured by any operative procedure. The callus thrown out after an operation might easily interfere with the function of the joint. The deformity which is the only objection to the present condition is, after all, not very marked nor will it attract much attention.

In discussion Dr. Dowd said that the wonderful good functional result in this case should be a lesson to all surgeons as to the amount of good that nature can do by simple conservative processes. Very seldom even after a great deal of interference, is as good a functional result obtained by the most carefully calculated methods. The case teaches how little we know in reality of the result of injuries at the elbow-joint.

Exostoses after Elbow-joint Injury.—Dr. Manley said that he does not think that we are quite justified in saying that there has been a fracture of the external condyle in this case. The olecranon seems to move on the proper articular surface. The projection felt at the back of the elbow might be new bone. It is well known how frequently new bone forms after injuries at the elbow-joints. The case serves to show the uselessness of the X-rays for absolute diagnosis in cases of complicated fracture or of dislocation and fracture. It is extremely easy to mistake the indications that are observed on an X-ray plate. To attempt to use radiograms as evidence in medico-legal cases is absolutely unwarranted. No better proof of this can be found than in the present case in which despite the carefully prepared Roentgen pictures, or best evidence can only be obtained from the old methods of palpation and manipulation. The younger generation of surgeons should realize that the old methods of diagnosis from the physical signs in such cases must be as carefully practised as before the introduction of the X-rays if they are to have any assurance of the value of their diagnosis.

Dr. Forbes Hawkes in closing the discussion said that he quite agrees with Dr. Manley as to the inutility in many cases of the X-rays in making an absolute diagnosis of complicated fractures. Within a few weeks he has had a classical Colles' fracture with all the typical symptoms, deformity, disability and crepitus. After reduction carefully prepared X-ray plates failed to show any sign of the lesion. In the present case, however, the physical signs seem to confirm the X-ray pictures as to the existence of a fracture of the lower end of the humerus in the original injury and the existence there now of a false joint which is responsible for most of the function which is present at the elbow. The combination of the two methods of diagnosis seems to justify the conclusion that this pseudo-arthrosis may often be of very great service in these cases.

Sarcoma of Testicle.—Dr. Pfister presented a very large tumor of the testicle which had been removed some six weeks ago from a young man aged twenty-two years. The tumor proved to be a sarcoma of the testicle and had reached its present size, some eight inches in length and five inches in transverse diameter, after only seven months of growth. The patient made an excellent recovery from the operation. Of course, the question of the possibility of the recurrence of the tumor cannot be definitely set aside as yet. Although the removal was very complete the prognosis is only reasonably good as these tumors are very prone to recur. The case is interesting also because the testicle on the right has never descended, and no trace of it can be found at any place in the genital canal. Usually in these cases it is the undescended testicle which undergoes malignant degeneration. The malignancy has usually been attributed to the constant irritation to which the organ is liable in its abnormal position.

In discussion Dr. Walker said that investigation of the literature of this subject of sarcoma of the testicle shows that the tendency of undescended testicles to undergo malignant degeneration is very marked. So marked, in fact, as to indicate an operation for bringing down an undescended testicle.

Acute Intestinal Obstruction.—Dr. Parker Syms said that this is always a fatal condition unless relieved. It is also a mechanical condition and requires mechanical treatment. The diagnosis is easy, if the symptoms are considered. Once the diagnosis has been made the question of treatment has to be seriously and promptly considered. The condition demands relief as soon as possible, spontaneous recovery may take place by a miracle through the formation of an artificial anus, or intestinal anastomosis, but these occurrences are extremely rare and should not enter into our routine consideration of the affection at all. No cathartic should be given. It adds to the danger. Short of surgical procedure, the only treatment justifiable is the giving of high injections. Even these must not be allowed to delay recourse to surgical procedure. The indication is for laparotomy, as soon as possible after the diagnosis has been confirmed and the inutility of injections demonstrated. Just as soon as the general practitioner realizes this state of affairs the mortality from acute intestinal obstruction will become much less than it is. Opium should not be given. It serves only to mask the symptoms and cause the operation to be delayed unwarrantably.

Technic.—When the vomiting is persistent and projectile in character, general anesthesia has too many dangers. Persistent vomiting can often be relieved by washing out the stomach. While opium should not be used in the early stages of the affection, it should be given as soon as operation has been definitely decided upon. It not only helps the action of the local anesthetic, but is the best stimulant that we have for shock.

Microbe Virulence in Intestinal Obstruction.—Dr. A. A. Berg called attention to the fact that during the time the intestinal contents are retained above the point of obstruction, the intestinal micro-organisms were apt to be rendered in-

tensely virulent. It is well known how intensely emaciated patients may become after only a day or two of suffering from the affection. This was formerly attributed to the shock persistently present, but seems really to be due to the intensified pathogeneity of the microbes in the intestine. The statistics after the operation for intestinal obstruction are bad, mainly because of this virulence. It does not seem advisable then to close up the intestine at once after the obstruction has been removed or even to make a direct end-to-end anastomosis. It is better and more conservative surgery to make a temporary artificial anus and wash out the proximal and distal end of the intestine very carefully. After a day or two when the patient has reacted and the microbic virulence has been lessened, the resection of the intestine may be undertaken. An important thing for the shock in these cases is the infusion of salt solution into the circulation. This should be done, not in large amounts at long intervals, but in small quantities every hour or so. When given in this way the effect is much better and the tonic action more continuous.

Differential Diagnosis.—Dr. Manley said that not only is acute intestinal obstruction very rare, but it seldom lasts more than twenty-four hours. The case is a surgical one from the beginning. It is extremely difficult to differentiate between perforation of the intestines and acute intestinal obstruction. Practically, the only sure differential sign between the two conditions is that in perforation the liver dulness disappears owing to the presence of gas in the peritoneal cavity. Enemata should be given very carefully, not in large amounts and never under much pressure. The intestine is often diseased and may easily give way with a fatal issue. In a recent case Dr. Manley found that a practitioner who had injected a gallon of soapsuds had caused a perforation of the intestines, and on laparotomy the abdominal cavity was found full of soapsuds, sweet oil and excrementitious material.

Dr. Boldt said that there is often considerable difficulty in recognizing when operation must be done. In a recent case, that of a child of twelve, he operated some months ago for perforative appendicitis in which there had been considerable inflammatory reaction in the formation of a good many intestinal lesions. Despite the great care in preventing the reformation of the adhesions, the child became ill some months later with symptoms of intestinal obstruction. The vomiting became persistent and on the second day fecal in character. Notwithstanding this the general condition remained reasonably good. Under the use of enemata the child recovered somewhat. The vomiting grew less, the temperature came down, and the pulse became normal. There was no tympanites. After a day or two the vomiting returned, tympanites developed and considerable tenderness was found. On laparotomy the obstruction was found to be due to a band of adhesion; extensive peritonitis was present. Despite the most careful manipulation the serosa was torn. Eight inches of bowel were resected and an end-to-end anostomosis with a Murphy button made. He then tried to push some of the feces from above the obstruction onward through the button, but found he could not do so. Another anostomosis was then made, but without resection. The patient made a good recovery. At least the child is well now, six days after the operation. As to keeping the bowels quiet after an anastomosis operation for acute obstruction, Dr. Boldt does not believe it advisable. It gives too much chance for the absorption of toxic materials, and the stasis of substances within the gut is liable to decrease intestinal vitality. The ordinary anastomosis is sufficiently strong to stand peristalsis and the movement of material through the intestine and such movement should be carefully provided for as soon after operation as possible.

Dr. Willy Meyer said that it is his custom to press out the excrementitious material from the proximal end of the intestine. There is always an accumulation of material, usually in an intensely fermenting condition, just above the point of obstruction and this should be gotten rid of as soon as possible after the opening in the intestine is made. The intestine should be placed on a set of warm sterile towels for this purpose in order to avoid any infection of the peritoneal cavity.

The Hockey-Stick Incision.—Dr. Willy Meyer described this form of incision which is meant to enable the operator to reach any complications that he may find in cases of appendicitis. The incision is made from midway between McBurney's point and the anterior superior spine of the ilium down to where the femoral artery can be felt pulsating beneath Poupart's ligament. Into this incision the finger is introduced and carried directly across to where the epigastric artery can be felt pulsating. The incision is then carried with a rounded angle at its lower part straight across with the finger in the wound as a guide. This gives it the form of a hockey-stick and enables the operator to reach any complications that may exist in the small pelvis. It serves its purpose very well in all cases, except in very fat patients. In women, particularly, the lower part of the incision gives very good access to the small pelvis if there should be complications in the uterus or its adnexa. In males it is very useful for the drainage of the small pelvis. Dr. Meyer has used the incision in ten cases now and feels that he can recommend it with confidence.

Posterior Rectus Sheath Incision.—Dr. Joseph Wiener, Jr., said that the most available incision for complicated cases is the cutaneous incision alongside the rectus muscle with the incision of the posterior sheath of that muscle. This may be enlarged up and down to any extent required in order to treat complications.

In closing the discussion Dr. Willy Meyer said that a long incision at the side of the rectus muscle divides the nerve supply of the muscle which is so important for the nutrition of the structure in after-life. We have come to realize of late years how much depends upon trophic nerve in-

fluences for the tonicity of muscle and its proper nutrition and function. The hockey-stick incision has not this disadvantage of severing the nerve supply of important muscles and it may be made longer or shorter to suit the circumstances of the case.

Twisted Omentum as Tumor.—Dr. Peck presented the specimen of a tumor which had filled the whole right side of the abdomen from above the umbilicus to the small pelvis. It was found to be composed of the whole of the omentum twisted on itself into a tight roll by the motion of the intestines. It was free except for some recent adhesions, which could be separated easily, and some very firm adhesions in the pelvis. These firm adhesions had evidently existed for a long time and were the true cause of the twist. With both ends of the omentum anchored fast the peristaltic movement in the intestines had rolled the omentum upon itself, as could be seen in the specimen. The symptoms of the case were rather sudden in the onset and resemble somewhat those of strangulated hernia. They were evidently due to the fact that the twist in the omentum had finally become tight enough to shut off the blood supply.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held Tuesday, February 6, 1900.

The President, Frederick Peterson, M.D., in the Chair.

Tendon Transplantation in Infantile Cerebral Palsy.—Dr. B. Sachs presented a boy fourteen years of age, one of the original cases of infantile cerebral palsy reported some years ago by Dr. Peterson and himself. He had had a typical cerebral hemiplegia, due to difficulties at birth. The boy called at the clinic because of contracture of the arm. A transplantation of tendons was done by Dr. W. R. Townsend, with a very gratifying result. These cases seem to him to hold out even a better prospect of recovery than the ordinary infantile spinal cases, because in spite of the contractures much more power is left in the various groups of muscles.

Dr. W. R. Townsend exhibited two photographs showing what was the position of the hands and the limbs of extension and flexion of the fingers and wrists at the time the boy first came under his observation. The method selected was to transplant the extensor tendons on to the flexor tendons. The electrical reaction of the flexors was diminished. The anterior pair of the four muscles reacted slightly. On December 21st, under ether anesthesia, an incision was made in the middle of the flexor surface of the arm over the wrist; then the flexor carpi radialis and flexor carpi ulnaris were divided above the wrist and held temporarily by silk sutures. The next step was to make an incision on the dorsum of the wrist and expose the extensor communis digitorum one inch and a half above the wrist. A dissection was then made between the bones so as to connect with the tendons previously cut. The extensor communis digitorum was folded back, as it was too long, and transplantation to the attachments of the flexor carpi ulnaris, radialis and palmaris longus was then made. All the dressings were removed at the end of six weeks, since which time the arm was carried in a sling. The arm is now held in a posistion midway between flexion and extension, and there is a fair grasp, although there was none before the operation. Before the transplantation the hand was helpless and useless. If proper exercises are used the boy will be almost sure to have a useful hand, and will be able at least to use a pen.

Dr. Leonard Weber presented a case for diagnosis as to the mental condition of a man thirty-five years of age, a clerk by occupation. The family history shows a marked tendency to mental disorder. In the spring of 1895 he began to be troubled with slight vertigo, drowsiness, headache and occasional fainting spells. He became somewhat erratic in his habits, and on August 10th developed an attack of acute mania. In November the speaker first saw him while still confined in a private asylum. In December he was transferred to the Bloomingdale Asylum, and in the following May was discharged, the physicians there looking on the case as one of acute mania that recovered. Some months later the man exhibited symptoms of malarial infection and responded fairly well to quinine. He was then put tentatively on mixed treatment, but with negative results. Early in December, 1896, he had a slight serous pleurisy. Some time afterward Dr. Weber located a subphrenic abscess, and, on incision, over one pint of pus was evacuated. The man's recovery was uneventful, and on January 1, 1897, he resumed active work, and has continued at his occupation ever since that time. The patellar reflexes are diminished, and sexual power is lost. The case is presented with the idea of determining the cause of the mania—whether it resulted from an infection.

Amyotrophic Lateral Sclerosis.—Dr. E. D. Fisher reported the case of a woman, forty-nine years of age, who gives a history of mental disorder in her immediate family. The patient presents no evidence of syphilitic infection. She was very ill in each of her two pregnancies, and after the last confinement, which occurred sixteen years ago, she suffered from neuralgia of the leg. In December, 1898, she noticed some difficulty in talking, and ten months later speech failed entirely. About this time she first noticed some difficulty in passing the bolus of food into the back part of the mouth. On December 20th she came under observation. At that time there was inability to speak or swallow, and the jaw was rigid. The tongue was small and short, and rather rigid. Examination showed the same rigidity throughout the muscular system. The first diagnosis was bulbar paralysis. The tone of the voice is now entirely nasal; the tongue small, and the muscles of the neck and jaw so rigid that the

mouth can only be opened slightly. There is an increase of the reflexes. Swallowing is difficult. The rigidity of the tongue and the increase of the reflexes are the special features of the case.

Dr. C. L. Dana suggested that the case is one of amyotrophic lateral sclerosis.

Dr. Joseph Collins concurred in this diagnosis, and said that he reported an exactly similar case in 1892, the spastic condition of the neck and face having been the most pronounced and the initial symptom. From this he inferred that the primary neurons decay before the motor neurons.

Dr. Fisher said that he would accept the diagnosis suggested by the last two speakers.

Diplegia Brachialis Traumatica.—Dr. Pearce Bailey presented a man, fifty-four years of age, who was knocked down and injured by a carriage last December. Two ribs were fractured, and both upper extremities became paralyzed. He was treated for a short time at Roosevelt Hospital. On coming under observation, in January, 1900, examination showed the movements of the neck to be free and painless. The muscles about the shoulders were paralyzed and atrophied, and responded sluggishly to faradism. He complained chiefly of severe pains running down from the shoulders into the arms. There was no paralysis of the legs or the bladder and no anesthesia. The diagnosis was diplegia brachialis traumatica. Kocher maintains that this condition is the result of an extradural hemorrhage, basing his opinion apparently on the existence of the darting pain down the arm. Dr. Bailey thinks there might be compression of the nerve-roots, or hemorrhage into the cord itself. He does not think an extramedullary hemorrhage will cause such symptoms as existed in this case, and, moreover, such a lesion occurring as an isolated one is practically unknown.

Dr. Max G. Schlapp thought if the lesion be due to hemorrhage into the cord there would be more marked sensory disturbance.

Dr. Collins thought the chances are enormously in favor of this condition being hematomyelia. It does not seem to him at all probable that the rapid atrophy of the muscles could result from an extramedullary lesion; it is rather a true atrophic condition dependent on the destruction of some of the motor cells at their origin.

Dr. E. D. Fisher thought that there is not a destructive lesion in the anterior horn, but slight capillary hemorrhages.

Dr. Schlapp thought the hemorrhage must be on both sides in the anterior horns, and if they were so large as to cause such atrophy they must also affect the anterior commissure and the gray matter of the anterior horns.

Dr. Mary Putnam Jacobi did not see why there should be any more marked sensory symptoms here than in an anterior poliomyelitis.

Dr. Percy Bolton said that he had seen quite a number of cases, the great majority having been apparently due to lesions into the spinal cord. Last year, however, he saw one case in which the symptoms pointed to injury of the nerve-roots in the foramina. This patient fell on his head, and entered the hospital with tingling sensations in the distribution of the ulnar nerve. On flexing the head on the trunk the tingling sensations in the arms could be developed, and this led to the supposition that the nerve-roots were involved.

Paralysis of Serratus Magnus-Gliosis.—Dr. William Hirsch presented a man who came under his observation about two weeks ago. The patient said that for two years past he suffered from what he called "an itch on the abdomen." Examination revealed the fact that in spite of the itching complained of there were no scratch-marks visible. There is an area of disturbed sensation on the abdomen. Its upper border is formed by a horizontal line passing through the ensiform cartilage, and the lower border is formed by a horizontal line about six inches lower down. The lateral boundaries are the axillary lines. Further inquiry shows that there is no true pruritus, but a paresthesia. This area is extremely sensitive to heat and cold. Closer examination shows bilateral paralysis of the serratus magnus, as indicated by the wing-like projection of the scapulæ when the arms are held forward and horizontally. There is atrophy of the trapezius and of the latissimus dorsi. The patellar reflexes are normal. These muscular affections must have developed quite rapidly, as the man was examined not long ago by a thoroughly competent physician in a hospital. He assumes that there is here a lesion in the posterior horns in the eighth or ninth dorsal segments, probably a neoplasm, a gliosis. This gliosis by occlusion of blood vessels and the consequent increased blood pressure might have caused the formation of a cavity. Another theory is that the primary gliosis has been too slight to cause any symptoms, but that by proliferation the effect observed has been produced.

Dr. R. G. Wiener said that this patient was sent to him about a week ago for diagnosis. The man is a glazier by occupation, and anyone who is accustomed to work with the hands above the head is likely to suffer from paralysis of the serratus magnus. Careful examination of the affected area, when the patient's attention was distracted, led him to look upon the paresthesia as purely hysterical. The muscular paralysis seems to him entirely peripheral.

Dr. Hirsch expressed great surprise at this diagnosis. There is only one case in literature of peripheral bilateral paralysis of the serratus magnus. Moreover, there are no sensory disturbances in the upper region. He could not reconcile the diagnosis of hysteria with the known pathology of the case presenting such symptoms. The affection of the other muscles made such a diagnosis in his opinion utterly impossible. The comparatively long duration of the case certainly does not exclude a gliosis.

Ophthalmoplegic Migraine.—Dr. B. Onuf presented a young girl who for the past five years has suffered from attacks of pain in the right

upper eyelid, associated with nausea and vomiting. Soon after the beginning of the attack the eyelid began to droop, and in the course of three days the eyelid was closed and the eye appeared to be fixed. After remaining closed for about three days, the eyelid opened again and the pain disappeared. Lately these attacks were less frequent, there being only about three in one year. Examination shows paresis of all the muscles supplied by the third and fourth nerves, but the rectus internus acts well. The attacks are preceded by constipation and chilliness. The case is looked upon as one of ophthalmoplegic migraine.

Dr. W. M. Leszynsky said that he would rather call the case one of recurring ocular palsy. He had seen one case in which there were two attacks in one year. She ultimately recovered completely.

Dr. Onuf replied that vomiting, periodic pain, and the associated tachycardia seemed to him to stamp the case as one of migraine in addition to the ocular palsy.

Paresthetic Meralgia.—Dr. P. Meirowitz presented two men. The first was forty-eight years of age, and first came to him on January 23d, complaining of a gnawing sensation on the outer aspect of the thigh. There were also alternating sensations of heat and cold. Examination shows no objective changes in the appearance of the skin. Over the area, beginning three inches above the external condyle, and extending upward for some distance there is anesthesia to touch, and immediately surrounding this is a region of tactile hyperesthesia. In portions of the affected region the strongest faradic current does not cause the slightest inconvenience.

The second patient was forty-seven years of age, and was first seen on January 6th, when he complained of a burning sensation on the outer side of the left thigh. The trouble came on suddenly eight or ten days previously, and was at first on the anterior aspect of the thigh. Occasionally the sensation is that of hot water boiling under the skin. Just above the knee is an area of anesthesia to cold. The affected area feels cooler to the touch.

Dr. C. L. Dana said that it has been very properly stated by Dr. Meirowitz that these cases are not at all rare. He has seen a similar condition affecting the calves of the legs on both sides. Probably paresthetic meralgia can be found in the distribution of most of the nerves.

Intracranial Tumor.—Dr. Graeme H. Hammond reported a case of this kind. The only lesion discovered at autopsy was an epithelioma growing from the sella Turcica. It measures 7½ by 2 by 1½ mm. The median line of the tumor corresponds very closely with the median line of the skull. It compressed both optic nerves, the optic chiasm, part of both optic tracts and the third, fourth, fifth, and sixth nerves on both sides, both crura, the hypophysis and the inner surface of both temporal lobes. Microscopical examination had not yet been made. In October, 1897, this woman, thirty-four years of age, presented herself, and a diagnosis of encephalic tumor was made. She had a good personal history. About fifteen years ago she had a fall on the back of the head, but this was not followed by any evidence of injury. Some years before coming under observation she began to suffer from a tic in the face, which was relieved by extraction of several carious teeth. Shortly after this the articulation became imperfect for a time, and soon innervation became impaired. In August, 1897, she suffered every morning from intense pain in the top of the head, and later on vomiting was quite troublesome. In October, 1897, examination showed the pupils to be regular and dilated, and responsive to accommodation. The eyeballs moved normally, but showed slight nystagmoid movements. She could not read fine print. Sensibility was normal. The ophthalmoscope revealed optic neuritis. During the next year the same symptoms were present, but to these severe headache, vertigo and a staggering gait were added. In September, 1899, weakness was noticed in the left arm and leg, and after a time a well-marked hemiplegia developed. In January the limbs were rigid, and the reflexes exaggerated. Sensibility was normal in all parts of the body, and smell, hearing, and taste were normal. There was a well-marked double optic neuritis. The tumor was thought to be situated in the motor fibers of the right hemisphere. At the husband's request an operation was performed, although no hope of a successful result was entertained. The tumor was not found, and the patient never rallied from the operation. The remarkable feature is that such a large tumor, pressing on so many cranial nerves, should not give rise to symptoms which would make the location diagnosis reasonably certain. A search through the literature shows the reports of several cases in which tumors similarly situated gave rise to no focal symptoms.

Dr. Sachs said that he has had under observation for the past two years a case giving very much the same symptoms, and he was impressed with the paucity of the usual symptoms of tumor of the brain. The only symptom added of late was double anosmia.

Myelitis, Especially Tuberculous.—Dr. Joseph Collins read a paper with this title. He said that acute myelitis is relatively uncommon. The case reported is that of a woman, twenty years of age, who was admitted to the City Hospital in 1898. Her illness began about three months before its fatal termination, the first thing noticed being a redness and painful swelling of the second metacarpophalangeal articulation. The question arises whether these symptoms are really due to rheumatism or to vasomotor changes. A few days later the right elbow became painful and swollen, and in a few days more the other elbow, one ankle and one knee were successively involved. According to the history she had been treated in Bellevue Hospital for rheumatism. On reaching the City Hospital she had a number of large bed-sores of long-standing. She was pregnant at

the time, and was soon after delivered of a child, which is now living. It was noted shortly afterward that the limbs were absolutely fixed, that there was urinary incontinence, but no sensory disturbances. The cranial nerves were not affected. About two weeks before death there were rigors and elevations of temperature, indicative of septicemia. The autopsy was made twelve hours after death. The spinal canal contained pus up to the second lumbar vertebræ, and from this point upward was a layer of greenish exudate, which reached up to the brain and forward to the optic chiasm. The cord was very much softened between the sixth and ninth segments. The lungs were free from tuberculosis. Microscopical examination of the spinal cord shows the changes to be most marked in the eighth and ninth segments, and least marked in the cervical cord. From one end of the cord to the other the dura is the seat of productive inflammation, and this is true, to a lesser extent, of the pia. The sections made from the eighth dorsal segment show the central area of necrotic tissue limited in front by the commissure. One of the sections from this segment shows a few tubercle bacilli. No bacilli are found in the meningeal exudate. The changes in the ganglion cells are those of advanced diffused chromatolysis. In many of the cells there is a complete disappearance of the achromatic granules. The cells most affected at these levels are those of the internal groups of the anterior horns. Sections from the first lumbar segment show the thickening of the meninges and the inflammatory exudate, and also congestion of the blood-vessels of the anterior horns. The changes in the chromatic granules and the achromatic substances are apparently secondary to the extensive changes in the blood-vessels, and not dependent on rheumatism or tuberculosis. Sections from the various lumbar segments stained by Nissl's method, show variable disintegration and degeneration of the cells of the anterior horns. The processes of the cells show a degeneration similar to that of the bodies. The so-called dislocation of the nucleus of the cell does not seem to indicate to any extent the pathological state to which the cell had been reduced. The changes in the cells of the cervical cord were similar to those in the lumbar region, although less pronounced. Many of the cells are large and stained deeply, while the achromatic substance in the cells is in good condition. The enormous thickening of the pia at this level is well shown in sections stained with hemotoxylin. The cells of the anterior horns show slight disintegration of the chromatic substance only. As the dorsal region is approached the cells of the anterior horns show more marked degeneration changes. Here the remarkable feature is the relative preservation of the cells of Clark's column. In conclusion, the speaker said that he did not believe that the pain in the extremities was the result of rheumatism, but of tuberculosis.

Dr. Schlapp said that the first drawing exhibited shows a very large lesion, which seemed to him difficult to explain by the clinical history, particularly in view of the fact that there were no sensory symptoms. He would like, therefore, to know whether it is not possible that this large lesion might be the result of post-mortem change.

Dr. W. H. Leszynsky suggested that it is possible that the large bed-sore over the sacrum might have had something to do with the septic process and the meningitis.

Dr. Collins replied that he commented, in his paper, upon the point raised by Dr. Schlapp, and had stated that, in all probability, this necrotic area was increased perhaps one-third by an artefact.

REVIEWS.

The Refraction of the Eye. Including a Complete Treatise on Ophthalmometry, a Clinical Text-book for Students and Practitioners. By A. Edward Davis, A.M., M.D., Adjunct Professor of Diseases of the Eye in the New York Post-Graduate Medical School and Hospital, Assistant Surgeon to the Manhattan Eye and Ear Hospital, etc. Illustrated. New York: The Macmillan Company, 1900.

In spite of a somewhat misleading title, which would indicate a work on the optical principles underlying normal vision and on the methods of determining and correcting ametropia in its various forms, the manual under consideration will be of practical value to those students and practitioners who wish to familiarize themselves with the use of the ophthalmometer and to understand the theory of its construction. To this extent the book can be recommended, although even in the chapters on ophthalmometry, which form the greater part of the volume, exception might be taken to some explanations. Thus the author's analysis of the correction of ophthalmometric readings and his rules for determining approximately the amount of total astigmatism do not appear to be as exact or as rational as those recently formulated by Javal. The diagrams which accompany the considerations on astigmatism make the entire subject quite intelligible, and form a valuable graphic aid in instruction. As far as the subject of refraction is concerned it must be admitted that Dr. Davis's work is somewhat inadequate. The ophthalmoscopic and retinoscopic methods of determining ametropia are but briefly mentioned, while the trial-case and the ophthalmometer occupy positions of undue importance. The author's opinion that cycloplegics are almost always unnecessary, and his statement that he does not use a mydriatic in more than one per cent. of all cases of refraction will, doubtless, bring tidings of great joy to the "opticist" and "refractionist," however cold their reception by members of the medical profession, who are informed that even spasm of accommodation is not considered an indication for the use of homatropin or of some other cycloplegic. The style of this treatise is rather

careless. Such expressions abound as "many times" for "generally," "Waaelaston" prisms, "cross" cylinders, "oval" for "elliptical," "if" for "whether," "fitting the patient to glasses," "a prolonged time," "to add an increase;" while loose construction, repetition, and a pleonastic use of "that" are noticeable. Aside from these blemishes Dr. Davis's work may be considered a good guide to ophthalmometry. It should not be entitled a text-book on the refraction of the eye.

An American Text-Book of Surgery. For Practitioners and Students. By Phineas S. Conner, M.D., Frederic S. Dennis, M.D., William W. Keen, M.D., Charles B. Nancrede, M.D., Roswell Park, M.D., Lewis S. Pilcher, M.D., Nicholas Senn, M.D., Francis J. Shepherd, M.D., Lewis A. Stimson, M.D., J. Collins Warren, M.D., and J. William White, M.D. Edited by W. W. Keen, M.D., LL.D., and J. W. White, M.D., Ph.D. Third edition, thoroughly revised. Philadelphia: W. B. Saunders, 925 Walnut street, 1899.

The appearance of a new edition of this admirable work is to be regarded with unqualified pleasure by all those engaged in or about to commence the study of surgery, for its position is unique in the pedagogical literature of the subject. Probably no other book of the class in the English language is quite so well adapted to the needs of the student, and when the rapid advances of surgical science during the past few years had somewhat outstripped the older issue, in spite of the ever increasing multiplicity of new books offered, the thoughtful instructor was rather at a loss as to what to recommend to his pupils as a substitute. Now that it has been submitted to the pruning and amplification that the swiftness of medical progress demands it may confidently be commended as being fully representative of the science and art of surgery as it is practised by the most advanced operators of today.

In addition to a chapter on the use of the Röntgen rays in diagnosis, among the new topics introduced are a full consideration of serum-therapy, leucocytosis, post-operative insanity, the use of dry heat at high temperatures, Krönlein's method for locating the cerebral fissures; Lorenz's and Hoffa's operations for congenital dislocation of the hip, lumbar puncture, the forcible reposition of the spine in Pott's disease, the treatment of exophthalmic goiter, gastrectomy, several new methods of operating on the intestines, the use of Kelly's rectal specula, the surgery of the ureter, Schleich's infiltration method, the newer methods of disinfecting the hands, the use of gloves, etc.

The sections on appendicitis, on fractures and on gynecological operations have been revised and enlarged and a considerable number of new illustrations added throughout the book.

In spite of the fact of its being a compilation the work is remarkable for its homogeneity and compactness; so skilfully has the work of collating and revising been done that there is a conspicuous absence of the feeling of abrupt transition and imperfect annotation that so often mars the result in similar volumes, when the writings of many authors have been simply juxtaposed and bound between the same pair of covers without the exercise of that rigid sense of the fitness of things which is the whole art of editing.

Borrowing the sacred formula of the ancient prescriber it might be said that the work is to be warmly commended to all those who would acquire their learning *cito, tuto et jucunde;* quickly because the text is concise and well arranged, safely for it represents the teaching of the masters of the science, and pleasantly for the style throughout is agreeable, the illustrations excellent, and the print and paper above reproach.

A Practical Treatise on Materia Medica and Therapeutics. By Roberts Bartholow, M.A., M.D., LL.D., Professor Emeritus of Materia Medica, General Therapeutics and Hygiene, in the Jefferson Medical College of Philadelphia; Honorary Fellow of the Royal Medical Society of Edinburgh, etc. Tenth edition, revised and enlarged. New York: D. Appleton and Company, 1899. Pp. xxii-866.

To reach the tenth edition, a text-book must possess inherent merit and any irrelevant matter must have been eliminated from its pages. And when the author of a work on therapeutics himself has a thorough faith in the power of drugs, he is bound to impress his readers with a desire for extensive knowledge of therapeutic resources. Bartholow believes in drugs and concentrates his energies on finding for them a practical use in medicine. He seldom speaks disparagingly of a drug, and often contents himself with merely stating the uses to which the remedy has been put, without attempting a discussion of its relative merits and demerits. The present edition is of the same size and arrangement as its predecessors, with the addition of a short chapter on prescription-writing and the metric system. The latter system the author commends, yet does not use it in stating the doses of drugs. The list of newer synthetic remedies has had some additions, and the work generally has been brought up to date. Three pages are devoted to antipyrine, but half a page to phenacetine: a whole page is all too little for saccharin, and a short paragraph must suffice for beta-naphtol. For the latter substance no internal use is assigned, and its derivative, benzo-naphtol and beta-naphtol bismuth, are not mentioned. The topical application of guaiacol in tubercular peritonitis, hydrocele, epididymitis and orchitis is not spoken of, and among the compounds, guaiacol carbonate and valerianate are omitted. Although a derivative of narcotine, cotarnine hydrochloride, used to arrest hemorrhage, seems out of place among the opium preparations, and methylene blue is sadly confused with methyl blue, or blue pyoktanin. The articles on urethane and paraldehyde are very commendable, the frequent failure of the former drug being attributed to insufficient dosage. Ich-

thyol is well treated, especially as regards its recently developed use in internal medicine. The newer silver antiseptics and iodoform substitutes are discussed at some length, and nitroglycerin is hailed as a "sine quâ non" in the treatment of anemia. The strengths of the pharmaceutical preparations are not stated, the reader being left to arbitrary doses to determine the relation of one preparation of a drug to another, or of either to the drug itself. No reason is given why the maximum dose of the fluid extract of digitalis should be three minims, while the 15 per cent. tincture of the same drug may be given in dose of one dram. The range of dose of fluid extract of ipecac is from two minims to one dram, while that of the 10 per cent. wine of ipecac is one minim to one dram. The book is essentially a work on therapeutics, the materia medica part of it being apparently added for the sake of completeness. And in spite of a few errors that have crept in, we can recommend it to the student or practitioner as a valuable work on the means of curing disease. Its arrangement is pleasing, its descriptions are interesting and clear, and it covers the subject in a very satisfactory manner.

Treatise on Orthopedic Surgery. By DR. E. H. BRADFORD and DR. R. W. LOVETT. Second revised edition. 8vo., 655 pages. Illustrated. New York: Wm. Wood & Co.

IN this second edition the more notable additions are as follows: Calot's operation for the correction of the deformity of Pott's disease; forcible correction in the treatment of scoliosis; coxa vera and fracture of the neck of the femur in childhood; the modern treatment of congenital dislocation of the hip; tendon-grafting for the relief of paralytic distortions; and an extended account of the prevention and treatment of the acquired disabilities of the foot. The illustrations have been carefully selected, those showing the various pathological processes being especially commendable. The new edition fully sustains the reputation of its predecessor as the standard work on this subject.

BOOKS RECEIVED.

The MEDICAL NEWS *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* MEDICAL NEWS *will shortly appear.*

THE NERVOUS SYSTEM OF THE CHILD. Its Growth and Health in Education. By DR. FRANCIS WARNER. Cr. 8vo. 233 pages. Illustrated. The Macmillan Company, New York and London.

A SYSTEM OF MEDICINE. By many writers. Edited by DR. T. CLIFFORD ALLBUTT. Vol. IX. Mental Diseases and Diseases of the Skin. 8vo. 998 pages. Illustrated. The Macmillan Company, New York and London, $5.00.

ANNUAL REPORT OF THE SUPERVISING SURGEON-GENERAL OF THE MARINE HOSPITAL SERVICE OF THE UNITED STATES for the fiscal year 1898. Washington, Government Printing Office.

THE CRIMINAL. His Personnel and Environment. A Scientific Study. By A. DRAHME. Demi 8vo. 402 pages. The Macmillan Company, New York and London. $2.00.

A DICTIONARY OF TERMS USED IN MEDICINE AND THE COLLATERAL SCIENCES. By R. D. HOBLYN. 13th edition by DR. JOHN A. P. PRICE. 8vo. 838 pages. Lea Brothers & Co., Philadelphia and New York. $3.00.

TRANSACTIONS OF THE TEXAS STATE MEDICAL ASSOCIATION. Thirty-first Annual Session. Held at San Antonio, Texas. 8vo. 348 pages. H. A. West, M.D., Galveston, Texas, 1899.

TRANSACTIONS OF THE LOUISIANA STATE MEDICAL SOCIETY. Twentieth Annual Session. Held at New Orleans, La. 8vo. 176 pages. H. G. Gessner, M.D., Secretary, New Orleans, La., 1899.

TWENTY-NINTH ANNUAL REPORT OF THE BOARD OF COMMISSIONERS OF PUBLIC CHARITIES OF THE COMMONWEALTH OF PENNSYLVANIA FOR 1898; also the Report of the General Agent and Secretary, Statistics, and the Report of the Committee on Lunacy.

NERVOUS AND MENTAL DISEASES. A Manual for Students and Practitioners. By DR. CHARLES A. POTTS. Pocket Text-Book Series. 12mo., 455 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York. $1.75.

TWENTY-FOURTH ANNUAL REPORT OF THE MANAGERS AND OFFICERS OF THE NEW JERSEY STATE HOSPITAL AT MORRIS PLAINS. For the year ending October 31st, 1899.

CONSUMPTION AND CHRONIC DISEASES. A Hygienic Cure at Patients' Home of Incipient and Advanced Cases. By DR. EMMET DENSMORE. 12mo., 198 pages. Illustrated. The Stillman Publishing Co., New York.

HOME NURSING. Modern Scientific Methods for the Care of the Sick. By EVELEEN HARRISON. 12mo., 235 pages. The Macmillan Company, New York and London. $1.00.

TRANSACTIONS OF THE MEDICAL SOCIETY OF NEW JERSEY. 1899. 8vo., 411 pages. Dr. W. J. Chandler, Secretary.

MT. SINAI HOSPITAL REPORTS. Volume I. for 1898. 8vo., 341 pages. Illustrated. 1899.

TRANSACTIONS OF THE AMERICAN PEDIATRIC SOCIETY. Eleventh Session. Vol. XI., 8vo., 250 pages. Illustrated.

NORDRACH AT HOME, or Hygienic Treatment of Consumption. By DR. JOS. J. S. LUCAS. 12mo., 60 pages. J. W. Arrowsmith, 11 Quay street, Bristol.

CLINICAL STUDIES IN VICE AND IN INSANITY. By DR. GEORGE R. WILSON. Demi 8vo., 234 pages. The Macmillan Company, New York. $3.00.

SIXTH ANNUAL REPORT OF THE BOARD OF MANAGERS OF CRAIG COLONY AT SONYEA, N. Y. To the State Board of Charities.

THE INTERNATIONAL TEXT-BOOK OF SURGERY. By American and British Authors. Edited by DR. J. COLLINS WARREN and DR. A. PEARCE GOULD. Volume II., Regional Surgery. 8vo., 1072 pages. Illustrated. W. B. Saunders, Philadelphia. $5.00.

SURGICAL PATHOLOGY AND THERAPEUTICS. By DR. JOHN COLLINS WARREN. Second edition. 8vo., 873 pages. Illustrated. W. B. Saunders, Philadelphia. $5.00.

ORIGINAL ARTICLES.

MYOCARDITIS IN INFANCY AND CHILDHOOD.[1]

BY HENRY KOPLIK, M.D.,

OF NEW YORK.

WERE we to judge of the frequency of myocarditis in infancy and childhood from the space devoted to the consideration of this disease in the pediatric text-books, we should rank it as rare and scarcely worth serious study. Yet all, or most all of our knowledge on the pathology and theory of myocarditis to-day has accumulated from observations upon the infant and child. The pathological anatomy of the condition certainly has received most of its facts from autopsies upon infants and children dying of the infectious diseases. The theoretical experimental work upon the myocardium has received its direction and stimulus from these autopsies. The classical book of Henoch treats of myocarditis in small paragraphs, relative with the infectious diseases; true, in a masterly manner, but yet not so as to impress the student with its ever present importance. From the standpoint of daily practice, it would not be overstatement to say that myocarditis, if not the most trying, is one of the most important conditions met at the bedside of the sick infant and child. It is sometimes the only thing that stands in the way of the recovery of the patient.

In the literature we are first struck with the uniformity with which the various workers in the pathology of myocarditis have established the presence of serious heart-muscle changes in autopsies upon infants or children dying of the infectious diseases. Any autopsy upon diphtheritic, scalatinal or typhoid material will uniformly show changes serious enough to have caused death. From the classical epoch-making work of Virchow to the convincing proof brought forward by Romberg, Hayem and Leyden, we find a uniformity of result. It would be out of place here to recapitulate changes in the myocardium established by Virchow, Romberg, Leyden and Hesse in the infectious diseases of infancy and childhood. Every well-read physician is familiar with them. It is, however, of the utmost importance to remember that Romberg found these changes to exist only in foci and not to affect the whole myocardium, as we would have the parenchyma of the kidney affected in acute nephritis. In other words, portions of the heart may be quite normal, others degenerated, in a fatal case of myocarditis.

Of greatest interest to the practising physician are the results of experimental work in the sphere of myocarditis. It has long been a question whether the temperature, the toxins, or the bacteria, individually or combined, were the cause of the myocarditis in the acute infectious diseases. T. W. Talquist, B. Werhofsky, Wm. Schamshin, Welch and Flexner, and J. Mollard and Ch. Regaud have given us very interesting data in this direction. As I have stated, they have been for the most part guided by the results found at autopsy upon infants and children, and have tried to produce similar conditions of fever and toxemia in their experiments on animals. B. Werhofsky has raised the internal temperature of the healthy animal by external means. He eliminated toxemia as much as possible and showed that heart changes, such as parenchymatous degeneration of the muscle cells, are undoubtedly produced by prolonged fever. The changes are not sufficiently marked, however, to account for the advanced myocarditis found in the infectious diseases. He concluded that the myocarditis found in these diseases is only in part due to the fever, and for the most part to toxins. To demonstrate that a toxin alone can cause fatal myocarditis, he has killed animals with abrin toxin. The changes in these cases consisted in marked parenchymatous myocarditis (cloudy swelling and fatty degeneration being very advanced). It would require much more space to go fully into the experiments with diphtheria toxin and its effect upon the parenchyma of the various organs. The leading facts can only be touched upon here.

The works of Welch and Flexner, Mollard and Ch. Regaud are of especial interest in relation to our theme. Mollard and Regaud, experimenting with the toxin of diphtheria, have found that animals injected with this poison not only showed an invariable parenchymatous degeneration in acute forms of intoxication, but sometimes this was the only lesion found after death. The muscular fibers were affected; they lost their striation and showed cloudy swelling. The nuclei and cytoplasm became affected. The vessels also were the seat of marked changes. In subacute poisoning, the interstitial form of myocarditis was added to the above picture. Leucocytosis in the acute toxemia was found in foci. These leucocytes, then, designate the phagocytes of elements of degenerating and disintegrating muscle-cells.

T. W. Talquist attempted to find out whether bacteria (in his experiments, streptococci) could, of their own activity, cause myocarditis. He came to the conclusion that streptococci find a bad culture nidus in the myocardium, and soon lose their activity. They do not proliferate, but die out after a time in the tissues. The toxins produced

[1] Read at the General Meeting of the Academy of Medicine, January 18, 1900.

by them cause parenchymatous changes which in subacute cases may be supplemented by interstitial changes. All changes start from the pericardium or zones immediately adjacent.

Of still greater interest are the experiments of Wm. Schamshin, who examined the nerves and ganglia of the heart, with a view to determining whether the clinical symptoms of myocarditis could be connected with changes in the nerves, rather than in the muscle. He came to the conclusion that the nerves showed no changes whatever; the muscle-cell itself, primarily, was the seat of degeneration, and symptoms must be attributed to the presence of these changes. Making autopsies upon children who died of diphtheria and who had been treated with serum, he found that the late cases, only after the disease had lasted three days, showed parenchymatous changes. This fact is of the greatest significance in view of the modern tendency of the antitoxin treatment of disease.

I have thus sketched in broad outlines the doctrine of myocarditis in the acute infectious disease. Myocarditis is an entity, distinct, always threatening, and sometimes fatal in these conditions. The myocardium is peculiarly susceptible to the action of any toxin, whether it is that of abrin or that of the diphtheria bacillus. The fever plays but a subordinate rôle. This latter fact must impress itself on the mind of the physician; for some of the most toxic and fatal diphtherias or pneumonias run their course with a low fever demanding no therapeutic measure of itself. The symptoms, so far as the heart is concerned, are not due to changes in the nerves or ganglia primarily, but to lesions of the muscle-cell itself.

From a study of the literature we are impressed by the fact of the universal presence of heart changes at autopsy. This forces us to the inevitable conclusion, important to the physician, that myocarditis is more frequent than supposed, and is not only a great factor in the semiology of the infectious diseases, but is not always fatal, as the text-books upon pediatrics would lead us to suppose. In other words, a heart may have been the seat of myocardiac changes and still in the end be restored to the normal. The infant or child's heart must be particularly capable of restoration to the normal, if we consider the great number of infections it withstands before the advent of adult life. There may be conclusive experiments in the future which will justify the belief of Zenker, Waldeyer, and Hayem, that the diseased muscle fiber of the heart is capable of regeneration in the same manner as the injured nerve fiber, else we would have the vast number of adult hearts the seat of disease as a result of the repeated toxemias of infancy and childhood.

This brings the writer to the clinical part of myocarditis. We will consider the disease only as it occurs in the acute infectious diseases, and will not touch upon the myocarditis occurring in conditions of diathetic dyscrasias, such as congenital syphilis and tuberculosis. It would be impossible to formulate, with our present knowledge, any definite semiological table of symptoms which in the infectious diseases could be traced to a latent or marked myocarditis. If this were possible, our work at the bedside would be much more intelligent; we would hear less of sudden fatal issues to diphtheria, pneumonia, or other exhausting diseases. The original disease masks the symptoms referable to the heart. To-day we have a certain definite set of symptoms which supervene after the myocarditis has been well established. They may appear at the outset, as in diphtheria and endocarditis, or in the convalescence, as in diphtheria, typhoid fever, or pneumonia. The symptoms point, as a rule, to some functional weakness of the heart muscle, as evinced by feeble, disordered action of the organ.

One of the most striking effects of the serum therapy in diphtheria has been the uniform assertion of those whose observations are worthy of consideration of the great supporting action of the injections. On the second day after the injection, a child will be found sitting up and playing in bed, while the throat is still covered with membrane. What may this mean? It is that the toxic action of the disease has been arrested not only on the various organs, but upon the muscle fiber of the heart. Hesse, in pre-antitoxin days, proved that sudden death supervening at the outset of this disease from acute myocarditis, was not uncommon. Schamshin, on the other hand, has shown that myocarditis in serum cases is found only after the disease has lasted three days or more. Symptoms of functional cardiac disturbance may appear in the convalescence, not only of diphtheria, but of any severe throat disease of the streptococcus or staphylococcus variety. The following case will illustrate:

A female child, six years of age, had passed through a severe pseudo-membranous throat affection of a streptococcus type. The child was still confined to bed. In the early morning while sitting up to take her breakfast she was suddenly taken with faintness, a chilly feeling, vomiting and great precordial distress. On reaching the bedside I found the external temperature reduced to the touch, the pulse very irregular, flickering, and not rapid. With the application of restoratives the little patient did well, but these attacks of faintness and cardiac irregularity continued for months after the disease had run its course. The child made an eventual recovery to the normal. This was without question a cardiac affection due to the toxic action of the disease on the heart muscle.

I have to-day under constant observation a boy of four years of age. When a baby nine months old he had suffered from a severe and prolonged attack of malarial poisoning. The plasmodium was found at that time in the blood, but only after the disease had lasted some time. The temperature during the first period of the disease reached the maximum of 106.5° F. in the rectum. After prolonged convalescence, dur-

ing which the infant and afterward the child was allowed to be the subject of repeated attacks, we find to-day the following condition: A well-nourished child for his age, he is not over fat. When free from symptoms his color is very good. His pulse has an irregularity not more marked than is common to children. He is subject to attacks of weakness. He becomes pale, his hands feel cool, his heart is very irregular and sometimes his sickness compels him to leave his play and lie down. The mother, who is very intelligent, has observed him during these attacks. His pulse is flickering and very irregular. These attacks will come on even during sleep; a cold perspiration will break out over his face and the extremities are cool; no temperature; no enlargement of the spleen; no blood plasmodium; no cardiac abnormalities except a weakness as apex of the first sound. Quinine not given at these times. The conclusion, in view of the excellent condition of this boy between these syncopal attacks, the absence of cardiac valvular disease, has been, for me, that the prolonged malarial poisoning has left the heart muscle compromised. It may eventually be restored to the normal.

The pneumonias of infancy and childhood furnish their quota of disturbances of heart action, which may point to very serious effects of toxins of the disease upon the heart muscle. Of the primary pneumonias, functional derangement is apt to appear at the time either of the onset, at the appearance of the crepitant râle or at the time of the crisis or convalescence. I have often seen at the outset of the pneumonia, an infant overwhelmed by the disease. Such infants may be over fat; they bear illness very badly. There are at the outset evidences of poor heart action in a pallor, with slight cyanosis, rapid heart action. It is impossible in such cases to say whether we have a primarily fatty, weakened organ, or distinct changes in the myocardium due to infection, or whether the organism is overwhelmed with the disease. In the beginning of convalescence, however, at the time of the crisis, such a case as the following is apt to cause great uneasiness. The presumption of myocarditic change is very strong. The following case is illustrative:

A boy, eight years of age, suffering from a most severe lobar pneumonia, right lower lobe, with marked cerebral symptoms at the outset. The cerebral symptoms persisting throughout the disease. At the time of the crisis the temperature fell to subnormal; without any previous symptoms, irregularity of pulse set in to a very marked degree, so much so that the pulse was thready and seemed to threaten to stop. There was some precordial uneasiness. The systolic apex-beat was weakened and the second pulmonic sound somewhat intensified; no signs of cardiac dilatation. This boy caused great uneasiness for days, and for a time into the convalescence.

On the other hand, the following case in which an autopsy was made will be of interest: A boy, nine years old, suffering from an acute osteomyelitis of the tibia, after a week's illness developed quite suddenly a pneumonia of the right lung lower lobe. When seen by me his pulse presented gallop rhythm; his respirations were much accelerated; there was cyanosis, pallor and great precordial uneasiness. The boy looked mortally ill. The heart gave the most interesting signs. At the apex both sounds were very indistinct. The muscular part of the first sound was scarcely appreciable. There was a very slight valvular quality to the second sound. At the pulmonic valve there was slight accentuation of the second sound. A diagnosis of great cardiac weakness was made; possibly heart clot. The autopsy, two days after, in addition to the pneumonia and osteomyelitis showed a somewhat flabby heart; a microscopic examination was not made, although it in all probability would have been found degenerated, arguing from the macroscopic consistency.

The most interesting class of cases and yet those which some would least be willing to admit as belonging to this category of myocarditic changes are the severe cases of pertussis. The writer has shown that in these cases the heart is subjected to great strain. Henock speaks of fatty degeneration of the heart muscle in prolonged and complicated cases of pertussis. Osler speaks of the strain on the heart and its possible etiological factor in producing heart disease later in life. In my own work on heart strain in pertussis I showed distinctly that the cardiac area was increased in many of these cases, although it was impossible to positively prove that dilatation of the ventricles existed. The heart action in all of these cases is weakened and insufficient. There is a constant dyspnea and constant pulse acceleration even between paroxysms, constant drowsiness, edema of the face and extremities, all showing cardiac insufficiency. Auscultation even shows slight blowing murmurs at the apex and weakness of muscular sounds. There are other evidences in these cases of cardiac insufficiency, such as pallor and cyanosis, weakness and disinclination to exertion, such as mounting stairs. The pulse is not only increased, but markedly irregular and dicrotic with sustained tidal waves. The evidences of strain and consequent weakness of the myocardium, and, as Henoch put it, fatty degeneration, are overwhelming. They are the result not only of strain during the paroxysms, but the effect of the toxic influences of the disease itself.

In complicated cases the toxemia is increased by the complicating conditions. A very large class of cases in which the integrity of the heart muscle is seriously compromised are those in which the patient is the victim of endocarditis or pericarditis.

The prognosis of rheumatic cardiac affections is much more favorable in infants and children than in adults. In other words, it is common in infants and children to find murmurs, the result of healed or past endocarditis, giving no symptoms. The heart and

economy do not seem to suffer much from these healed conditions. They are found incidentally to examination for other affections. In acute endocarditis, in the active stages of the disease, most observers have been able to make out a palpable increase in the relative cardiac dulness. This dulness diminishes in the convalescence, and if the disease is cured, the heart areas are found normal. Not so should the heart be the subject of a subacute process or repeated attacks of endocarditis. The dulness will increase very palpably. Added to this will be found other evidences of heart weakness. Such hearts are apt to act very unsatisfactorily upon the supervention of any infectious disease, such as measles or scarlet fever. I have seen such hearts become very insufficient, the swelling of the liver and spleen become more marked. In the convalescence and thereafter attacks of vomiting and faintness supervene, the swelling of the liver is apt to persist and attacks of cardiac angina and precordial distress are frequent. So great is the recuperative power of the heart in children that such cases may even retrograde, the liver diminish in size, the attacks of angina subside, the heart action become quieted; in other words, signs of degenerative effects may disappear. Such a case is now under my observation.

A girl, aged fourteen years, who has been the subject of simple endocarditis since an attack of measles in infancy, and under constant observation. Two years ago she had an attack of scarlet fever. The above signs of cardiac inefficiency appeared and persisted for months, finally to disappear, leaving only the signs of the old endocarditis.

The most trying cases of heart weakness with degeneration of muscle fiber are those of adherent pericardium. In most of the cases the changes in the pericardium are combined with those in the endocardium. The degenerative changes in the muscle fiber of the heart are more serious than in any other form of rheumatic heart disease. There is actual destruction of muscle fiber and its replacement by connective tissue. The following is a case in point. The history of rheumatic endo- and pericarditis extended over two years. The boy, six years old, after repeated attacks of endo- and pericarditis developed an attack in which signs of heart weakness were extreme. The respirations and pulse ran up to an abnormal degree, the pulse and respiration ratio being 2 to 1 for weeks. He died with all signs of progressive cardiac weakness: post-mortem revealed marked interstitial myocarditis starting from the pericardium principally and very marked increase of brown pigment in the interstitial tissue, and also in the spaces between the muscle cells of the myocardium.

Possibility of Diagnosis During Life.—The question which will arise in the minds of most physicians is whether the diagnosis of myocarditis can be made positively during life. The literature shows that the most extensive myocarditis has been found at autopsy, and yet during life no symptoms referable to the heart were noticed. This fact, and also the fact that the most serious cases of myocarditis first show their presence by the sudden death of the patient in apparent freedom from symptoms, has engendered a pessimistic attitude toward the conditions which we have described. This attitude is harmful. It is not in accord with the advances in our knowledge. If we cannot make a positive diagnosis, we may suspect in a great many cases the presence of myocarditic changes in the face of certain symptoms. If the fatal cases have baffled our methods of recognition, we have a large number left in which certain symptoms of cardiac weakness should put us on our guard.

If, in the course of an infectious disease, we have attacks of faintness, pallor, vomiting, disturbed and very irregular heart action, a persistent distortion of the respiration and pulse ratio as in adherent pericardium, it is certainly significant, especially if these attacks have a tendency to recur. If examination of the heart shows extreme weakness of the apex beat, weakness of the first sound, or disappearance of its muscular quality, greater intensity of the second sound at the apex, with intensification of the second sound at the pulmonic orifice, we certainly in these have danger-signals of greatest moment. If, in addition, as in pertussis, we have other signs of cardiac insufficiency, such as a slight systolic blow at the apex, edema of the face and extremities, pallor and cyanosis, disinclination to exertion, constant drowsiness, it would be certainly narrow, in view of our pathological and experimental knowledge, not to entertain the possible existence of serious degenerative changes in the heart muscle.

The daily labor of the physician is at the bedside of the infant and child suffering from the infectious diseases. He may be unconscious of the fact, but the recovery of his patient will in the vast majority of his cases depend on the action and integrity of the heart muscle. His therapeutic methods must not simply reduce temperature, but in reducing temperature they must not compromise the utility of the heart in order that the patient may tide over the dangers of the illness. In all this we must foster the modern tendency of treatment which is to support the strength of the patient. The danger which hovered over patients who formerly were given large doses of depressant drugs can be appreciated, if we believe what has been brought forward in this paper. As to the heart, we should never forget that it is fortunate that even in a degenerated organ we have healthy tissue on which our drugs and methods are supposed to act. We must not exhaust these healthy foci by overwhelming them with harsh measures or large doses of powerful drugs. Foster their strength rather. The areas of degeneration will not be aided by drugs, but must be healed; in time, possibly, there may be regeneration of new tissue. The hope of these cases then lies in well-sustained nutrition, carefully and persistently regulated.

UTERINE FIBROIDS COMPLICATED BY PREGNANCY.[1]

By WILLIS E. FORD, M.D.,
OF UTICA, N. Y.

A FIBROID tumor of the uterus does not necessarily imperil life. Its position, its size, and the rapidity of its growth are factors that must be taken into account when advising as to what treatment, if any, is necessary. Complications that arise from pressure, or from hemorrhage, or from degenerative changes, often demand radical measures. It is usually because of some of the complications arising from the presence of the fibroid that the patient first seeks the advice of a physician. Very large symmetrical fibroids of the intramural variety have been discovered by the physician before they were known to the patient. The position of the fibroid or its relation to the true structure of the womb is of more importance, perhaps, than the size of the tumor. A small fibroid in the top of the womb may remain for years without doing any special harm; whereas, a growth of the same size on the side of the uterus at the base of the broad ligament may interfere with the ureter so as to cause death. Again, the small fibroid embedded in the body of the uterus and projecting into its cavity so that its capsule is ruptured, may cause such troublesome and persistent hemorrhage as to warrant a hysterectomy. A soft myoma may give no pain and yet increase in size so rapidly as to endanger the life of the patient.

Pregnancy is one of the complications, rarer perhaps than others, but it is seen frequently enough to make it an interesting topic for discussion. It is probable that pregnancy takes place more frequently in a fibroid uterus than was formerly supposed to be the case. I am inclined to think that many serious conditions following normal childbirth are due to the presence of small unrecognized fibroids. It is very often the case that no examination of the uterus is made until the time for normal delivery of the child, and a fibroid easily escapes observation unless a most careful examination is made. I am inclined to think that pregnancy occurs less frequently in subserous fibroids than in the intramural class. Of course, a large submucous fibroid, if it is at all extruded into the cavity of the uterus, will naturally prevent conception. Again, a fibroid which involves either lip of the cervix enough to distort the cervical canal will probably prevent conception.

The dangers attending pregnancy where there is an intramural fibroid are overdistention and rupture of the imperfectly developed fibers of the uterus, or the prevention of the normal first stage of labor by the presence of the inelastic fiber tissue at the neck; or, displacement of the uterus so as to distort the natural birth passages; and, lastly, sepsis following infection after delivery. It is impossible to make a rule which shall define the limits of danger and prescribe what operative procedure shall be followed in the dangerous cases. I venture to relate a few typical cases that have come under my observation which seem to me to illustrate the conditions that may safely pass to normal delivery; and also to illustrate those conditions where surgical interference is necessary.

Case I.—In 1892 a young woman was sent to me with a fibroid tumor of the intramural variety involving the body of the uterus, chiefly on the right side. The cervix was free. The tumor extended half way to the umbilicus. The woman was well in every way and had no hemorrhages, but wanted to discuss the advisability of an operation. She declined to be operated on and was treated for a time with ergot. In November, 1893, she was married, at the age of thirty-three. She miscarried at the second month in April, 1894. There was no infection following and she was not long sick. In January, 1896, I was called to see her and found her eight months pregnant, the tumor displaced over to the right side and easily distinguished from the sound uterine tissue. The fetus lay very high, the uterine wall was thin, the cervical region was free, although the tumor extended to the umbilicus. The fibroid came to the median line in front and the uterus seemed to have developed laterally to the left side, the fibroid forming the right lateral wall of the uterus. I prepared for a total hysterectomy, informing the family of the great danger, and awaited the time for delivery, which occurred in February. There was not much trouble with the first stage of labor, although it was a breech presentation, and when dilatation was accomplished the feet were brought down and the child was easily delivered. It was alive and healthy. The afterbirth did not follow and finally was found implanted in the right side near the fundus, at the top of the fibroid, as if laid on a shelf made by the projection of the fibroid into the uterine cavity. This was removed with great difficulty, but with as little violence as possible, and with thorough attention to antisepsis. The uterus afterward contracted and the patient made a good getting-up, although for about six months she had occasional bright hemorrhage. This did not amount to enough, however, to call for any special interference but was accompanied with some pain similar to after-pains. At the end of the six months she had a sudden gush of blood with great pain, and extruded a fibroid tumor the size of a cocoanut. She has since remained well. Menstruation has been regular but scanty. An examination made recently shows the uterus retroverted, but not much enlarged, the cervix tilted up under the pubic arch, and the body of the uterus easily made out. In the posterior right lateral wall are three small subserous fibroids not larger than a walnut seated above the internal os. The woman is in perfect health. This type of case rarely becomes pregnant, I think, and is one in which the danger of pregnancy is not very great. The reliance for safety of delivery was based upon the fact that the lower part of the

[1] Read before the Medical Society of the State of New York, Albany, N. Y. January, 31, 1900.

uterus was free and that none of the cervical tissue was involved. It was, therefore, determined that she could be delivered, and the only remaining danger was sepsis. I fancy, however, that this fortunate outcome is not often seen.

Case II.—I was called in April of 1899 to see a woman who had been sick for eight weeks following a miscarriage. The history showed that this was the first pregnancy in a young woman who, when three months advanced, was thrown from a bicycle while riding and was taken into a neighboring hotel, as she was so ill that she could not be taken home. She miscarried in two or three days. The afterbirth was not easily removed and septic symptoms supervened, continuing for eight weeks, at which time I was called to see her. She was profoundly septic, with a high temperature, with a feeble, thready pulse, and with a foul-smelling discharge which frequent vaginal douches and antiseptics had not improved. I found a tumor in the posterior wall of the uterus the size of a cocoanut, involving part of the posterior wall of the cervix and extending into the uterine cavity above. This mass was sloughing and I advised an immediate hysterectomy, which was declined. As a temporary measure I curetted away large masses of this fibroid and packed the uterus with gauze, hoping to relieve the immediate symptoms and then secure a hysterectomy. The tubes did not seem to be involved, and, indeed, the condition was one of local putrefaction. Any further operation was declined and after a few days the woman died. The trouble in this case seemed to be largely due to the position of the fibroid, which was low down in the body of the uterus, posteriorly, and the capsule of which must necessarily have been ruptured during the process of dilatation previous to delivery, rendering infection almost certain. If she had gone on to full time it is doubtful if she could have been delivered naturally.

Case III.—In August of last year I was consulted by a woman, thirty years old, who said she had a tumor and who seemed very ill. It was found that she had a fibroid the size of one's fist near the left cornu of the uterus, and that the uterus below seemed distended as if pregnant. She denied the possibility of pregnancy and for a month or two it was very hard to be absolutely certain of the condition. At the end of three months, however, there was no doubt and the patient was retained in the hospital for observation. She was really too ill to be at home or to be cared for out of the hospital. The nausea and distress were dreadful and several times the question of inducing an abortion was discussed. The uterus rose very high toward the last of her term, and the distention was so great as to incapacitate her from moving about. No other fibroid mass was to be found in the uterus and it was thought to be safe to wait for a normal delivery. This occurred without any untoward circumstances and with very prompt contraction of the uterus, leaving what seemed to me to be a much smaller fibroid than the woman started with.

Case IV.—A woman, aged twenty-nine years, in her first pregnancy at the fifth month, who had been told that she had a fibroid and that it would not materially interfere with labor, was taken suddenly ill with pain in the abdomen and with some rise of temperature, and I was summoned to a neighboring town to see her. She was so sensitive to touch that an examination had not been thoroughly made by her physician, who was entirely competent and had desired to do so. It was not until I had argued the gravity of this condition for some time that I was permitted even to attempt an examination. The abdomen was very tense and fully distended, and the cervix was found fixed and impacted by a fibroid about the size of one's fist arising laterally from the left anterior wall of the uterus, just opposite the internal os. The whole birth canal was so occupied with this impaction that it would have been impossible to have delivered anything out of the uterus. I tried to get permission to administer an anesthetic and see if I could dislodge the fibroid, saying that unless this could be done a hysterectomy seemed to be necessary at once. In view of the gravity of the circumstances I advised enlarging the consultation and called Dr. H. C. Coe of New York. He agreed with the proposition already made and suggested that she be taken to the hospital where an operation could be done at once. After she was brought to the hospital I was able to manage the case better, and the next day had her placed in the knee-chest position and with the help of two assistants succeeded in unlocking the fibroid from below the ramus of the pubis where is was lodged, and in shoving it up into the abdominal cavity, thus relieving the impaction. The pain continued, however; there was slight rise of temperature, and it was feared that the impaction which had remained several days might have started a process of necrosis. A second consultation was called for the purpose of determining whether a hysterectomy should not then be done. The patient was prepared for abdominal section, and when under ether it was discovered that the fibroid remained above the pelvic bone, and that the cervix was practically free from any fibroid thickening. The normal uterine tissue, which had stretched to accommodate the fetus, was sound. We declined to operate and put the woman in bed, and after several days of careful nursing the temperature fell, a normal condition came on and she was delivered of a healthy child. The delivery in this case was very troublesome owing to the fatigue of uterine muscle and its apparent inability to expel the fetus. Dilatation was fairly well secured and the forceps were put on high up and the child was delivered. The placenta was implanted on the right side, fortunately, and the fibroid was not infected; and although there was considerable laceration of the perineum, which was immediately repaired, no septic symptoms followed. The fibroid was not materially diminished, but it is not six months since delivery. The opinion that the delivery of a three-months' fetus

could not be secured through the natural passage while the fibroid was impacted was concurred in by the three men who saw her. After the dislodgment of the fibroid the risk of waiting for a natural delivery was accepted because the neck of the uterus was not involved, and because there was a sufficient amount of healthy uterine tissue on the right side posteriorly to allow of dilatation.

Case V.—Last year a woman, aged forty years, who had borne three children, was sent to me for examination. She was in the fourth month of pregnancy and had been complaining of pain that was unusual and had gone to her family physician, an excellent man, who had made an examination and found a fibroid tumor in the anterior wall of the uterus. This tumor was directly in the anterior wall, beginning at the cervical junc-

Fig. 1.

Fetus, placenta and its implantation; uterus and fibroid bisected.

ture of the vagina and protruding forward. It was larger than a cocoanut so that the uterus was shoved backward, and about all that could be felt in the vagina was a hard fibroid mass. There was but a small segment of the cervix that seemed free enough to warrant the supposition that it would dilate, and it was decided that a miscarriage could not be produced and that a natural delivery would be impossible. The question of allowing the condition to remain until near the time of natural delivery and then doing a Cæsarean section was discussed, but this plan was abandoned because there was not room enough above the fibroid in the anterior wall of the uterus to deliver the child safely, and it was thought that the fibroid would be infected by the operation. Dr. H. C. Coe also saw this case with me and concurred in this opinion. Supravaginal amputation of the uterus was done, an elastic ligature being placed above the point of incision, and the uterus and its contents removed entire. The patient made an uneventful recovery. A photograph of the fibroid shows the uterus split from before backward with the placenta attached. (Fig. 1.) The shrinking of the thin uterine muscle above, due to its immersion in alcohol, does not give a correct idea of the space in which the child rested above the placenta and fibroid. This case demanded operation more urgently than any that I have seen, and there was no doubt in the minds of some half-dozen good surgeons who saw the woman but that an operation was absolutely necessary.

Case VI.—Last year Dr. L. A. Van Wagner sent to me for examination a woman whom he had only seen casually and who had been under no medical care previous to her coming to the hospital. She had been flowing continuously for about a year, and the examination which had been made showed that there was a small tumor in the vagina and a larger one in front at the base of the bladder. She was forty-seven years old and weighed one hundred and eighty-five pounds. She said that nineteen years ago she had given birth to her first and only child. Labor began at ten o'clock in the evening and terminated at seven o'clock the following morning. She did not recollect that anything unusual had happened, and had no special medical care at the time or afterwards, although a physician was present at the time of the birth of the child. She was able to sit up on the ninth day and was about the house five or six days later. An offensive discharge followed labor, which was continuous, so that a napkin had to be worn for a long time. She had severe headaches and backache which also continued for a long time. She began menstruating three months after delivery and flowed excessively and had great pain, but after a time the periods became more regular, occurring every three weeks. On admission to the hospital she was found to be anemic, but otherwise in good health. She had a large, capacious pelvis, short, large vagina, and a relaxed perineum. A mass was found at the base of the bladder which was drawn down easily, came out of the vulva, and was found to be the neck of the uterus, about three inches long, torn across the posterior wall at its junction with the body of the uterus, so that the cavity of the uterus was entered through an opening large enough to admit two fingers. In this opening was a submucous fibroid projecting about the size of an egg, and having a pedicle attached to the anterior wall of the uterus. A male sound passed into the cervical canal and through the opening into the vagina showed no cicatrix of the cervix where any dilatation or tear had ever occurred, and a small circular os which had never been dilated. The wall was thickened and fibrous, both posteriorly and anteriorly, at the point of the rent, the tissue being perhaps an inch thick. (A photograph of this is shown in Fig. II.)

After removing the polypus and curetting the uterus, which measured four inches in depth, the half-detached neck of the womb was amputated and a new cervix made. The amputated neck was intact and was some two and a half inches long, and its dissection showed no scar-tissue and no evidence that it had ever been dilated. I am forced to conclude that this very rare case was one of spontaneous delivery of the child through the posterior wall of the uterus, before which the neck of the uterus was torn and a spontaneous recovery occurred. I think these photographs taken in connection with the history of the case show a unique condition

Fig. 2.

Uterus presenting at the vulva, the sound showing the rent in its posterior wall.

and a recovery the like of which I have never seen reported. It is probable that the fibroid thickening of the anterior wall of the uterus, which extended down so as to involve the cervix, made this uterus unable to dilate enough to admit and give exit to the head of the child.

The cases that I have related seem to me to be sufficient in number to indicate, in a general way, that the rule may be established that where the lower third of the uterus and the entire cervix are free from any neoplasm, the physician may safely await the result of the pregnancy, even if the fibroid is of considerable size. If a neoplasm of any considerable size is found opposite the internal os, especially if it is large enough to in any way block the birth canal, then the question as to waiting until the child is viable and doing a Cæsarean section, or whether a total hysterectomy must be done early, is determined by the position of the fibroid, whether it is in the anterior or posterior wall of the uterus. An impacted fibroid requires an early hysterectomy unless it can be released, or unless the fibroid is high enough up so as not to involve the lower third of the uterus to any considerable extent. The dangerous position for the fibroid is in the anterior wall of the uterus, low down, because it would be difficult to do a Cæsarean operation successfully at any time. A uterus sometimes ruptures because of a neoplasm of no very great size which involves the lower segment of the uterus and the cervix; and unless this accident is prevented by very early operation it is probable that in most cases of rupture of the uterus sudden death occurs and the cause will be found to be a fibroid tumor.

After a delivery at term or a miscarriage at any time if the uterus has a fibroid that becomes infected a hysterectomy should be done at once. In every case of fibroid uterus when pregnancy occurs the patient should be carefully watched, and especially if the neoplasm is in the lower half of the uterus. A subperitoneal fibroid, especially if it has a pedicle and is attached to the upper half of the uterus, is not likely to do harm unless sepsis follows delivery. Such a fibroid can be removed before delivery without necessarily producing a miscarriage.

TOXINS FROM A CHEMICAL AND PATHOGENIC STANDPOINT.

By A. E. AUSTIN, M.D.,
of Boston, Mass.;
Professor of Medical Chemistry in Tufts Medical School,
and
I. H. CORIAT, M.D.,
of Boston, Mass.;
Assistant in Medical Chemistry in Tufts Medical School.

At the present time, when advances in pathology and bacteriology are so rapid that books of to-day contain facts unknown a year ago, and when the habits and environments of bacteria as to food, temperature and moisture are almost as familiar to us as those of orchids and chrysanthemums, we are apt to attribute to the bacteria themselves the pathological changes, associated with each and every specimen; nothing could be more false than to attribute to the tangible thing which we can see, *i.e.*, the bacterium, the changes in tissue which are really due to the intangible thing which we cannot see, *i.e.*, the toxin, the product of the bacterium. The bitter almond is harmless under certain conditions; we can handle it, inhale it, even inject it into the blood without injury, but as soon as it enters the stomach, and its enzyme, emulsin, splits off the hydrocyanic acid, then it becomes extremely poisonous.

Thus, while bacteriology has been able to elu-

cidate many misty points in the history of disease, it has reached its limit and has nothing more to offer us; but now the chemist steps in and the question becomes a chemical one as Hoppe-Seyler predicted it would, years ago, when bacteriology was first introduced into the University of Strassburg, as a separate branch of study. The task of chemistry is, then, to determine the nature of these poisons produced by bacteria, and right well have many of her devotees, such as Brieger, Gautier and Nencki, attacked this problem; their work abounds with new-found facts.

For convenience, they have all agreed to call these substances, toxins, in contradistinction to ptomains and leucomains, although we must confess that the distinction is not so carefully drawn as we might wish. If we allow the term ptomain to represent the basic substances formed in decaying albuminous matter, as Selmi first used the term and which are composed of a mixture of neuridin, cholin, ethylendiamin, putrescin, cadaverin, etc., as Brieger has shown,[1] then we are allowed to use the term leucomain for those pathological products formed by the abnormal living cell, or living cell in a diseased state in the human economy. We have an example of this, for instance, in the excessive production of what is normal to a limited degree, xanthin, kreatinin, adenin, etc., which, of course, may be the result of a diseased process and not the cause. We can confine the term, toxins, then, to those noxious products of bacteria, formed in the animal body, or, what is quite similar, in pure culture, since the conditions of the latter are quite analogous as far as moisture, temperature, etc., go, to those in the former, while it is, of course, much easier to procure our toxins from culture than from blood or other fluids of diseased individuals.

These minute organisms like other living beings, take in nourishment which, in their bodies, is subjected to certain chemical changes, oxidation, synthesis, etc., by which the simplest as well as the more complex substances may be formed. We find an admirable illustration of this in the formation of alcohol by the yeast-cell from sugar, a noxious as well as a useful substance in proportion to the amount used. In an analogous way, we may have diphtheria of such a mild type that the individual may not be inconvenienced at all, or so severe that the life is endangered; all depends upon the amount of the toxin evolved by the bacillus and absorbed by the individual.

At this point it will be well for us to take an account of stock, so to speak, and to arrange in order what is known concerning these evanescent products of the micro-organisms of different diseases. We are not speaking now of serums, of which there are many in daily use; these from their method of manufacture must necessarily be made up of several substances and undoubtedly contain the diluted toxin or, as bacteriologists choose to call them, antitoxins. What we choose to call toxins are the extracted crystalline products from the pure culture, soluble in water and usually in the form of the chlorid.

From the staphylococcus pyog. aureus, Brieger[2] was able to obtain a toxin, in the form of a chloride, which reacted to all the alkaloidal reagents, but was not tested by injection into animals. In fact, Panum,[3] the Danish physiologist, should have the credit of first calling attention to this subject, having been able to extract from the pus of a case of septicemia an active poison of a chemical nature, and was able to demonstrate the toxic effects of certain microbic diseases were not at all different from those of vegetable poisons like strychnine or coniine. But Brieger was able to procure enough of these products to actually perform an elementary analysis and to demonstrate their chemical formulæ.

Armand Gautier[4] has summed up briefly and well the nature of toxin as follows: "All infectious microbes act upon the organism by the poisonous products or toxins which they secrete. These poisonous products are chemical substances susceptible of filtration, precipitation and resolution. These toxins are usually complex, made up of an alkaloidal material and a nitrogenous substance which is very active. The primary effect of all these toxins is rise of temperature, and probably all fever is produced by the agency of some one of them.

From the streptococcus Brieger was unable to isolate any characteristic toxin, but from the Koch-Eberth, or typhoid bacillus, he was able to obtain a toxin which, injected into a guinea-pig caused salivation, dyspnea, paralysis of the hinder extremities, dilatation of the pupils and diarrhea. This substance in the form of chloride reacted to most of the alkaloidal reagents. The same author has described a crystalline toxin which he has extracted from the tetanus bacillus, and which when injected causes all the symptoms of tetanus. Following these investigations further, we find that Roux and Yersin[5] were able to isolate from a Klebs-Loeffler bacillus culture an active toxin which, they claim, has many of the characteristics of an enzyme in that its activity is very much diminished when heated to a temperature of 58° C., and completely destroyed at a temperature of 100° C. The activity of this poison extracted is also comparable to that of enzyme in the excessively small amount necessary to produce results; it was thus proven that one-half of a milligram was sufficient to cause the death of a guinea-pig.

Later Baldi[6] found an active toxin in diphtheria cultures and regards this noxious principle as a substance replacing the sulphur in the protein molecule. In 1896 Brieger,[7] by a new method, here given, succeeded in extracting from antitoxin serum an active principle of which he was able to obtain .1 gram in 10 c.c. of the serum. From the bodies of the bacteria, after the culture media plus the bacteria had been filtered through a porcelian filter, he was able to obtain a powder of which 0.01 grams, suspended in water, would kill a guinea-pig in forty-eight hours.

Vaughn[8] has also been able to obtain from the culture of species of bacteria found in drinking water, supposed to have caused typhoid fever, an

active toxic principle, soluble in water, which does not respond to the usual reagents for albumen but possesses the characteristics of an alkaloid, yet there is a rise of temperature, abdominal distention and distress with tenderness. The animals fall upon their sides and have vomiting and diarrhea.

Methods of Extraction.—The starting point of all processes is first to concentrate the solution containing the cultures, either before or after filtration through an unglazed porcelain filter, which separates the bodies of the bacteria from their formed toxins. This concentration must always be done at a low temperature for obvious reasons, and, if an attempt is to be made to obtain them in their crystalline form, a small amount of hydrochloric acid is to be added so that the fluid shall react slightly acid. From this point the methods differ, and we have four distinct ways in which they can be isolated.

(1) Brieger's method, briefly stated, is, after concentration and filtration, to precipitate with an alcoholic solution of lead acetate, filter, remove the lead by sulphuretted hydrogen and evaporate to a syrup; this again is to be extracted with alcohol and the alcoholic solution to be precipitated with an alcoholic solution of mercuric bichlorid. This mercuric precipitate is now cooked out with water, freed from both alcohol and mercury and reduced to a syrup, neutralizing the solution carefully with soda, so that it shall react only slightly acid. This is again extracted with alcohol, filtered, the alcohol driven off, and the residue taken up with water which now contains the toxins in a pure form and the crystals are readily obtained by evaporation over sulphuric acid in a desiccator; or, we may add gold or platinum chlorid and obtain the double salt of gold or platinum and the toxin as a chlorid.

(2) In the method of Roux and Yersin, the liquid containing the toxin, after filtration through a Pasteur filter, is concentrated to a syrup, extracted with 80 per cent. of alcohol, the alcohol driven off by evaporation, 5 c.c. of water added and the whole poured into a dyaliser, and allowed to remain twenty-four hours, when the water in the outside glass is found to be very toxic.

(3) The method of Stas Otto, used so often for obtaining alkaloids from organic substances with which they are mixed, consists of cooking the cultures for an hour or so with a dilute alcoholic solution of tartaric acid, filtering, evaporating to a syrup, again extracting with alcohol (absolute), driving off the alcohol, taking up the residue with water and shaking respectively with acidified ether, alkalinized ether, and, finally, with ether containing ammonium chlorid.

(4) Brieger and Boer[2] have devised a fourth method which consists in the following procedures: Add to the culture media, after they have been filtered through porcelain, two times as much: 1 per cent. zinc chlorid solution, wash the precipitate and shake it up with a 3 to 6 per cent. solution of ammonium carbonate, add zinc phosphate until all is dissolved and a cloudiness from zinc phosphate results. Filter, saturate the filtrate with ammonium sulphate, dissolve the precipitate in water, and shake this with sodium sulphate, filter, and the toxins are found in the filtrate. Of these methods the first has proved inefficient in providing enough of the toxins for satisfactory examination, for two reasons: (*a*) Because the toxins are destroyed even by a very low temperature and are undoubtedly decomposed by the repeated use of sulphuretted hydrogen; (*b*) because unquestionably a part of the toxins are thrown down by the first precipitation with lead. The second method of Roux and Yersin is a bacteriological rather than a chemical one, and the resulting product is a mixture of various toxic products, one of which is albumose-peptone, which the alcohol fails to precipitate and which, upon being injected, causes many of the symptoms wrongly ascribed to the toxin. It is interesting, however, as showing that the microbic poison can pass through an animal membrane and that it is closely combined with albumoses, which are the constant constituents of culture media after inoculation. The third method is pronounced worthless by Brieger for the extraction of toxins, however useful it may be for the isolation of the vegetable alkaloids.

With the fourth method, we have had no experience, although it would seem to do away with the three difficulties of the first method, *viz.*, the use of heat, sulphuretted hydrogen and lead. We have also found that the sodium chlorid, formed by neutralizing the excess of hydrochloric acid by soda in the first method, is very hard to remove and the crystals are apt to render the crystalline toxins impure. These toxins, when once separated from their combination with the albumoses, are precipitable by all the alkaloidal reagents, such as phosphomolydic and phosphotungstic acids, iodates of cadmium-potash, gold and platinums chlorids, picric acid and bichlorid of mercury. Almost all of these precipitates are crystalline and the double salts, formed with platinum and gold, are generally chosen for elementary analysis on account of their greater stability.

Our own efforts were confined to the cultures of typhoid and diphtheria bacilli and consisted of the following experiments:

Experiment I.—One liter of culture of typhoid bacilli, filtered through a porcelain filter and obtained through the kindness of Dr. R. M. Pearce of the City Hospital Pathological Laboratory, was subjected to the process of Brieger and the final product was a few c.c. of a colorless liquid which gave none of the reactions of protein matter, but gave precipitates with the following alkaloidal reagents:

Gold chlorid, crystals; platinum chloride, none; picric acid, none; bis. potass. iodid, copious; cad. potass. iodid, copious; potass. iodo-iodid, none; mercuric bichlorid, none.

The crystals formed with platinum chlorid were long, yellow, needle-like bodies, often cross-

ing each other at various angles and resembling very much sheaves of wheat or very much similar to crystals of tyrosin as they are found in urine or from pancreatic digestion, and were much as described by Brieger as a double chloride of platinum and typhotoxin. These crystals were easily soluble in water and after all the substance had been precipitated by platinum chlorid, the crystals were lightly washed after drying, and then dissolved in water from which the platinum was removed by sulphuretted hydrogen. There resulted an absolutely protein free, colorless solution which, when allowed to evaporate over sulphuric acid, gave several centigrams of a crystalline substance whose general form of crystallization was that of a tetrahedron, absolutely colorless and perfectly soluble in water. In order to verify this substance still further .010 mgms. were injected into a rabbit weighing 1038 grams on March 6th, with no appreciable effect. On March 7th, .020 mgms, were again injected, also with no effect, and March 8th once more .040 with a similar result. On March 13th, at 1.50 the remainder of the substance, amounting to .1125 gms. was injected into the same rabbit with almost immediate results. Within ten minutes the respirations ran up to 460 per minute; in fifteen minutes after the injection there was paresis of the hinder extremities of such a nature that the rabbit could not stand, but lay upon his side. The legs could be feebly retracted when irritated by pinching or by touching them with a sharp instrument. Following this there was a discharge of liquid feces; the head was drawn back, and there were slight convulsions. At 3.30 the animal had recovered from the initial severity of the symptoms, but was kept under observation for the following week during which it was very sluggish, ate very little, had loose discharges mixed with mucus and blood, and on March 21st died, eight days after the first symptoms.

During the latter period of its life there was an ashen blue hue to the ears, reminding one of poisons producing methemoglobin, loss of pupillary contraction and slight trismus of the jaw. The temperature taken on the day of its death was 21° C. and there was a diazo of Ehrlich reaction in the urine, while the animal remained in a state of stupor. Five hours after death an autopsy was performed upon it with the following results: Peritoneum, covered with white patches and serous exudate upon parietal and visceral layers. Intestines, hyperemic but no evidence of any ulcerations. Kidneys, enlarged, pyramids very much engorged with blood. Cortex, normal. Spleen, much enlarged and also engorged with blood.

Experiment II.—One liter of pure culture of typhoid bacilli, unfiltered, was subjected to the Brieger process, but the process of purification was carried a little further as suggested by him: after the final removal of mercury in the former process, the solution was evaporated to a syrup, extracted once more with alcohol, the alcohol driven off, the residue taken up with water, the acid neutralized with soda, acidified with nitric acid and the whole treated with phosphomolybdic acid. This precipitate, composed of the double compound with the acid, was now washed, decomposed with neutral lead acetate, the lead removed, and the solution somewhat concentrated. In this was found the toxins, since the solution was absolutely free from protein substance, but still gave precipitates with the following alkaloidal reagents:

Gold chlorid, yellow, six-sided plates with some longer narrow plates which still maintained the pointed ends, thus preserving the general six-sided shape; platinum chlorid, needle-shaped crystals, arranged in a more or less definite sheaf-shaped form. Potash bis. iodat, amorphous precipitate. Potash cadmium iodat, amorphous precipitate. For want of sufficient material, no attempt was made to inject this product into an animal.

Experiment III.—One liter of diphtheria bacteria culture, grown for two weeks and filtered through porcelain, was treated by Brieger's method. The isolated product showed no reaction with Millon's reagent, gave no xantho-proteic reaction and failed to respond to the biuret and Adamkiewitcz tests, thus proving that it was absolutely free from protein matter. It gave, however, the following reactions: Phosphotungstic acid, heavy, copious, white precipitate; phosphomolybdic acid, heavy, granular precipitate; platinum chlorid, fine, granular precipitate. Allowed to evaporate over sulphuric acid, this substance crystallized in long flat plates of a slightly yellowish color, of which the amount obtained was .1486 grams.

May 10th, .025 grams were injected into a kitten weighing 652.5 grams without any appreciable effect. May 11th, .040 grams were injected into the same kitten, and the following symptoms came on almost immediately: There was general uneasiness, accompanied by salivation. On May 18th, in hopes that this toxin might prove efficacious in rendering the kitten immune, it was inoculated with a pure culture of the Klebs-Loeffler bacillus and a control kitten that we will call No. 2 was also inoculated with the pure culture, but not with the toxin.

Kitten No. 1, inoculated with both toxin and pure culture, died May 28th, after ten days of illness, characterized by great muscular weakness, but no paralysis. The autopsy showed a purulent infection with a few streptococci. The liver showed areas of hemorrhagic infarction and was slightly fatty. The mesenteric arteries were highly injected but otherwise the organs were normal. The control kitten, No. 2, died May 25th, having had during the meantime loss of voice, accompanied by great muscular weakness, paralysis of the lower extremities followed by paralysis of the upper, and great emaciation. There was also a discharge of dark blood from the nostrils. The autopsy showed the mesenteric arteries highly injected, the bladder full of urine

which contained albumin. The kidneys enlarged, injected glomeruli with areas of coagulative necrosis; the external surface was roughened. Liver pale with some fatty degeneration. No membrane of fauces or trachea.

Experiment IV.—One liter of a culture of diphtheria bacilli, filtered as before through porcelain, was treated by the Stas Otto method, using hydrochloric acid instead of the usual tartaric acid. The results were as follows: (1) The ether from the acid solution spontaneously evaporated gave .0024 grams of needle-shaped crystals. (2) Ether from the alkaline solution (NaOH) gave .0085 grams of plate-like crystals. (3) Ether from the ammonium chlorid solution gave nothing.

A third kitten was injected with the products of the first evaporation (1) with the almost immediate onset of symptoms which consisted of dilatation of the pupils, unaffected by light, paralysis of the lower limbs and a great acceleration of the respiration, but after an hour's duration the symptoms ceased and the kitten fully recovered. The residue from the second ethereal extract produced no effect, when injected.

Experiment V.—A liter of filtered diphtheria culture was precipitated by ammonium sulphat, the precipitate dissolved in a little water and dialysed twice to remove the salt. The resulting solution was precipitated with 95 per cent. alcohol and the precipitate washed with absolute alcohol and ether, then dried over sulphuric acid. The resulting product was a brownish powder, soluble in water, giving the following reactions:

Phosphotungstic acid, yellow precipitate; biuret, positive; Millon's reagent, positive; xanthoproteic test, positive.

Kitten No. 5 was injected, June 30th, with .100 grams of this toxic albumose. July 7th, with .200 grams and July 11th, with .400 grams. The chief symptoms were paralysis of the limbs and great irregularity of the respiration. The urine contained albumin and casts. The animal died July 12th, and the autopsy showed necrotic spots in the liver, lungs and speen.

Experiment VI.—One liter filtered diphtheria culture was treated by the Brieger method. The resulting substance consisted of long, flat, yellow crystals. The crystals were soluble in water and in solution showed the following reactions:

Biuret, faint rose; Millon's reagent, negative; exantho-proteic, negative; Adamkiewicz, negative; platinum chlorid, fine gran. precipitate; auric chlorid, heavy precipitate; mercuric bichlorid, heavy precipitate; phosphotungstic acid, copious precipitate; phosphomolybdic acid, copious precipitate; iodo-potass. iodid, fine gran. precipitate; potass. mecur. iodid, heavy precipitate; potass. bis. iodid, heavy precipitate; potass. cad. iodid, heavy precipitate; stannous chlorid, no precipitate; picric acid, no precipitate; tannic acid, no precipitate.

There was then injected into a rabbit .100 grams and there followed symptoms of restlessness and salivation. This continued until the next day, but the animal finally recovered. Whether these toxins replace the sulphur in the albumin molecule or not cannot be absolutely stated, but as albumose, of which the cultures largely consist, is never free from sulphur, it is to be doubted. It seems much more reasonable to regard them as proteids much like casein with its associated iron, corresponding to the toxin. As the cutures uncoagulated by heat, even in an acid solution, but are precipitated by ammonium sulphat, it is much more probable that they consist of albumose to which the toxins are bound much in the same way that the iron or phosphorus is bound in caseose or the digested casein. Another fact is also evident, that these toxins are much less stable than indol, skatol and phenol, analogous substances formed by the bacteria in the intestinal tract, but which can be easily separated from the feces by distillation, a process which utterly fails to procure anything from the cultures of pathogenic microbes. Heat is undoubtedly the great factor in this case. These experiments show also that they are much more tenacious than the ordinary alkaloids in their adherence to the substance with which they are combined since the Stas Otto process, used in one case, is amply sufficient to isolate practically the whole of the alkaloid in the one case while the amount of the toxin obtained was very slight.

A more intimate knowledge of these toxins is always obstructed by the tiny amount which can be obtained; under the most favorable circumstances only about 0.2 grams can be obtained from a liter of the cultures. Brieger has tried to overcome this by using enormous quantities for his extractions, but apart from the difficulties of manipulating such huge amounts, there is always a doubt whether we have actually obtained the true active principle when we know that one bad oyster may kill a human being or diphtheria be fatal in three days. We have, of course, the possibility that the bacteria produce their toxins much more abundantly in the living body than in culture media, that they grow with greater rapidity is very doubtful.

It seems almost beyond cavil that the substance which we obtain is actually the element which causes the changes in living tissue in disease from the similarity of symptoms observed, paralysis chiefly in the diphtheria toxin, and comatose condition in the typhoid toxin. The primary action of these bodies is evidently upon nerve centers of respiration and locomotion, the secondary or more remote action upon the liver and kidneys or organs employed in the elemination of these poisons. Our efforts to stay the progress of disease by preliminary injection of the extracted toxin in gradual increasing doses seems to have failed, although the disease in Experiment III. ran a different course in the animal injected with both the toxin and the culture, from that in the animal injected with the culture alone. The pathological changes were also somewhat different, but these may have been only accidental.

In closing, we beg to say that we have worked

over old chaff, and have nothing new to offer, but still remain convinced that the road to new discoveries in medicine lies along this line, and still following up this pursuit, we hope to overcome the difficulties associated with this isolation of toxins so that the amount may be much larger or the potency much greater.

ALCOHOL AS A GENERAL STIMULANT AND HEART TONIC; ITS USE TO THE ANIMAL ECONOMY IN HEALTH AND DISEASE.[1]

By T. J. HILLIS, M.D.,
OF NEW YORK.

(Continued from p. 452.)

Alcohol in Acute Disease.—One of five causes always contributes to the failure of alcohol in the sick room to-day, namely, to begin its use too early or too late; to give too large or too small a dose, or to be irregular in its use. Almost always one or more of these causes is the prime factor in its failure to accomplish the purpose for which it was given; then, again, to entrust its use to an incompetent nurse is another fruitful source of failure. The truth is, at the critical time, the physician alone must be the sole judge of the amount to be given, and this amount must be regulated by the effect produced; at the supreme moment he must be on the ground and on the firing line to take personal command as watchman and guardian of the interests of his patient if he is to hope for success. By directing the battle from his office and trusting to excited and inefficient subordinates, his efforts will fail as they have failed, and to-morrow he will contribute an article to a journal of hygiene and moral therapeutics as full of inaccuracies and bad judgment as was his treatment of the dead man who so recently passed from his charge.

In pneumonia there may come a time when a quick and ready stimulant will tide the heart over a crisis, when convalescence is easily established. When digestion is good and heart action satisfactory for the lung area involved, the temperature will generally take care of itself without antipyretics, and in most cases will be found to range from 101° to 104° F. In a case of this kind, temperature has not a world of importance and never has, as long as the heart remains true, firm and strong, and from 90 to 104 at the wrist. This case will get well on beef extracts and milk; it needs no stimulation other than the normal supply which a reasonable digestion can afford.

In typhoid, following the beaten track—a typical case—when the subject is young and stomach faithful, with a temperature curve following the course characteristic of this disease, from beginning to end no alcoholic stimulant is needed. In diphtheria, although the system may be profoundly affected by the poison, with temperature high or low, if the patient has good digestion, and he may have, he will pull through without alcohol.

The prime factor in all these cases seems to be the stomach, not the disease. The cases which demand alcohol and which will result fatally without its intelligent use are those of pneumonia in which the heart has done excellent work for five days and a half; when it did this work in spite of a persistent high temperature (104°-105.5° F.); when there is considerable lung involvement and cerebral symptoms attended with low delirium. At this stage the stomach has lost its desire for food and the heart begins to weaken. It will be observed the heart follows very closely in the footsteps of the stomach. Now, if this heart could be kept up to its work and pump the blood as usual through the lungs for twelve hours more, the crisis would be reached and could be passed in safety, but how can this be done, as we see the stomach in rebellion, refusing to digest anything. At this time there is a loathing for all kinds of food; the abdomen is tense and tumid from flatus that cannot be expelled, because the muscular layer of the bowel is paralyzed. Evidences of dissolution are beginning to be apparent on every hand, cold perspiration, feeble, rapid pulse and a general "moribundness," with areas of hyperesthesia. If something would be now administered that would quickly pass through the walls of the stomach and reach the circulation without preliminary digestion, and if that something contained the elements of food, or, by its transformation in the tissues liberated energy held in reserve, it would save the jaded heart which has now all but stopped by supplying it with power to enable it to continue its work for the ten or twelve hours when relief is sure to come, and nature again swing her own pendulum. Have we that something at our command at this supreme moment? We have, but the physician in charge is afraid to touch it in the fear that if his patient gets well he may become addicted to the drinking habit; besides, he does not believe in intoxicants any way and was grieved to see his patient drunk six months previous. On that occasion it was on the anniversary of his wooden wedding, after which he was sick and his physician remonstrated on the evil of intemperance and commanded him to put the bottle away, which he did. He was right then; he is wrong now. Then the whiskey was a depressant and a paralyzer—a poison—now it will act as a powerful tonic, food and a liberator of pent up force.

The physician is trying every known remedy to save his patient, but he is sinking rapidly. Digitalin, nitroglycerin and strychnine are in turn tried, but they all fail as they only whip a jaded

[1] Read at the 16th Annual Meeting of The New York State Medical Association, held October 24, 1899.

horse; he wants food rather than a whip and none of them can supply it. The physician sees death in the face of his patient, apprises the family of his fears and suggests that a clergyman be called, recommends the inhalation of oxygen gas as a final resort, says a few kind words to the family about a reunion in Heaven, and takes leave of his patient forever. A member of the family has heard of a case of pneumonia successfully treated by the timely use of alcohol; he was afraid to mention this fact to the physician, knowing his antipathy to the stuff; now that he has taken his departure, he runs after the man of whom he has heard so favorably. This physician administers one tablespoonful of old whiskey in preference to brandy (the latter having higher diffusion power, reaches the brain too quickly and is contraindicated) mixed with two tablespoonfuls of water and a little cracked ice. The dying man's stomach retains it; his heart beats 138 to the minute, full and feeble and somewhat irregular at the wrist. Part of his body is bathed in a clammy perspiration, his tongue is thick, his feet are cold, his face is pale and his eyes sunk. Ten minutes and the physician with finger on pulse gives another tablespoonful of rye with now only an equal quantity of water and ice as before. It is retained, as was the previous dose. It has no bad effect on the pulse, if anything it has improved it, so after five minutes he is encouraged to give another tablespoonful as before. He recollects that now during fifteen minutes he has given the sick man an ounce and a half of whiskey, and his condition has improved decidedly since he began the treatment, for the heart-beat is more regular and the pulse not so quick at the wrist.

His curiosity is now agreeably excited and he places his ear to the dying man's heart to find increased uniformity in strength. Sixteen minutes have elapsed since he first began the rye whiskey treatment: the pulse then was 138, now it is only 128 and firmer. He will give another tablespoonful and does as before, diluting it and with ice. Now eighteen minutes have elapsed, during which time the sick man has imbibed two ounces of whiskey. In two minutes he tries the pulse again; it is 123, firmer still and more regular, although not so full, but with higher tension. Now, he is eager to communicate the fact to the distracted family in an adjoining room, and it is that he feels encouraged and has a hope of the final recovery of his patient. An hour has passed since he began his stimulation with whiskey, which consisted of three ounces, but great changes have taken place during that hour; the patient's feet are not so cold; he speaks more coherently; the perspiration is drying up, color is coming back to his face and there is a new light in his eyes. His temperature is again taken; it is 102° F.; it was 104° F. one hour ago; his pulse is now 118, with a promise of more stability.

The physician is tired from his worry and vigil, but he is determined to give the sick man another dose of rye before he leaves for home, having now been by the bedside two hours. This time he gives him another ounce of whiskey—two tablespoonfuls, with an equal quantity of water, but no ice, with the request that he sip it slowly, to eat it, as it were. On taking leave of the family—and it is a pleasant leave-taking—he tries the pulse again; it is 114, increasing in force and beating with regularity. The man is beginning to have possession of his faculties as he grasps the physician's hand to bid him goodnight as he retires from the room. To the nurse the retiring physician says, "Give two ounces of light bouillon, not too hot, every thirty minutes until my return, in four hours, and if the pulse runs above 120, immediately summon me. According to promise he comes at the stipulated time, and is told that the patient slept soundly for two hours after the second dose of bouillon. The physician was quick to recognize a decided improvement; the temperature is now 99° F., the pulse 102, and the patient convalescing.

Alcohol in Chronic Disease.—When the human system is the subject of an organic lesion like fibroid, or tuberculous phthisis, there is a demand for fats. Substances, which when taken into the system, are easy of digestion and contain material out of which this fat is manufactured in the internal economy, are what is wanted and what must be supplied if the body condition is to be improved. Malted liquors are known to be substances of this class and lend great aid to the physician in his efforts to restore his patient to health. It is also known that the parasite with which the lung is invaded is living on diseased tissues—any other would speedily destroy it; the bacillus has not created the condition in the lungs, but has used the diseased tissue as a means of support and to propagate itself. It is possible with such a state of things that the parasite will devour and exhaust the media in which it lives; this can be accomplished only through an increased nutrition, and anything that will increase this nutrition must be looked on as a therapeutic agent of the highest importance.

Certain wines and the malted liquors are rich in saccharine matter and are as a rule acceptable to the stomach and easy of digestion. The alcohol which they contain needs no digestion; it is the herald which prepares the way and tones the stomach for the more substantial ingredients in the malted liquors, of which it is a part. Both, together, initiate a body condition that is favorable for the reception of other foods, such as broths and many forms of farinaceous and albuminous substances. In a disease like phthisis, the alcohol compounds, such as porter, ale and beer, are of great value if properly and efficiently administered, and must not be confounded with their disagreeable and disastrous effects when given to a healthy man whose system is already saturated with the material they have to offer, namely, carbonaceous and albuminous proteids. In the latter case they do harm, and, if persisted in, present all the pathological changes that are ascribed to chronic alcohol poisoning.

The difference between the sick man and the well man is most striking; the former is prepared physiologically to use up and turn to immediate account all the nutritive material that is in his simple or compound alcoholic beverage, while the latter is unconsciously, but not the less surely, destroying himself; he is giving his stomach double work, besides overworking his liver and kidneys in an effort to throw off the superabundance of material with which his blood is charged. This man cannot oxidize half an ounce of alcohol in twelve hours, whereas the other man can burn up four ounces in half that time. The conditions are different; one man's system is prepared to receive a form of food already digested and not any other; the other man's system is already saturated and repels, rather than attracts, the hydrocarbon material that is now offered already digested and under favorable conditions ready to give up its nutritive qualities to enrich the blood and nourish the tissues.

At a time of shock strychnine probably is more efficient than alcohol, as it has greater oxidizing power. It increases metabolism, as can be seen from its great output of carbonic acid. Nitroglycerin has a very limited application, and in the hands of ignorant practitioners does great harm, administering it as they do under the delusion that it is a heart tonic, while, in fact, it is a depressant and can only aid the heart when the vascular tension is high by lessening resistance to the systole. Digitalis and strophanthus each has its measure of usefulness, but neither can be strictly said to be a heart tonic and at times both do much harm, especially if the heart is not enlarged but feeble with considerable vascular resistance. The administration of oxygen is sometimes useful and often injurious, especially if its application is left to the discretion of an inferior nurse. After looking over the list of so-called heart tonics, not one of them can be said to act as such, with a single exception, that of nux vomica and then its field of usefulness is confined within very narrow limits, while alcohol must take its place with the natural stimulants, food, rest and oxygen.

Conclusion.—Never give alcohol in lingering diseases nor in convalescence from acute diseases if it irritates or upsets the stomach. The stomach is the clearing-house of the human system and it is of the first importance that it should always be in a position to transact business. Alcohol furnishes the grist for the police court and distributes free passes to the Island; it often makes a low form of sneak thief, but never a high-class burglar. Burglars, sneak thieves and murderers are, as a rule, temperance men; their vocation demands that such should be the case.

Alcohol is not so potent for good at a crisis to old topers suffering from acute or chronic disease, their systems do not respond readily to the stimulation and it is slow to produce the desired effect. In a subject of this kind, the alcohol is not so readily assimilated nor so completely oxidized as in those unaccustomed, or only moderately accustomed, to its use. The good effect of alcohol in these cases is always in the inverse ratio to the quantity consumed by the individual in time anteceding his indisposition.

Alcohol may be a poison to-day, in dose great or small; to-morrow, to the same man, it may be a physiological agent of the highest efficiency. The intelligent individual, through the guidance of his medical adviser, should be at all times and under all circumstances the judge of the time and quantity to produce a definite result. Alcohol is not an aid to longevity, although if used moderately it is not a hindrance; however, it may be said that, as a rule, those live longest who do not use it other than for its physiological effect. Never drink whiskey in hot weather with the ostensible purpose of cooling off; such a purpose is laudable, but the means employed will prove inefficient and illusive, as the quantity that would reduce temperature half a degree will have a disastrous effect in another direction. Never drink alcohol on starting on a journey, whether that journey be by riding or afoot; it is like filling the pockets with cobble-stones, under the delusion that they assist locomotion; it steadily retards progress, puts the body on the defensive, and continually makes demand for repetition of the alcohol. The alcohol thus imbibed by this constant repetition lowers the temperature, exhausts the body, and in every instance defeats the purpose for which it is taken. One-fourth of the chronic and about one-fifth of the acute diseases among the populace of to-day can be directly traced to this source. Alcohol has the power, physiologically, to raise or lower the temperature; it can do the same thing through pathological processes. It raises the temperature through its properties as a stimulant and tonic and by its virtue as a food. It lowers temperature by its inhibition on the oxidizing apparatus during the process of the transformation of fatty and carbonaceous products into heat, and is a conservator of energy and source of economy to the body.

Pathologically, alcohol raises the temperature by deranging the heat distribution apparatus, irritating the vasomotor inhibiting supply of the peripheral arterioles, effectually shutting off insensible perspiration, and producing a dry, burning skin and a thin, rapid pulse. This condition is described as sunstroke and can take place without the aid of alcohol, but the best specimens are furnished by the assistance of this drug. Alcohol lowers temperature by its direct paralyzing effect on the vascular filaments of the sympathetic, widely dilating the peripheral arterioles and retarding the venous return from the body surface.

Never drink whiskey before delivering a temperance lecture or preaching a sermon; it will develop ideas but cannot formulate them; it will loosen the tongue and increase loquacity, but it will impair the reasoning powers and weaken the judgment.

Whiskey is a necessity to some people after a great mental or physical effort, as the brain-cells

are exhausted and functionate with difficulty. Alcohol jumps through the walls of the stomach, mounts the circulation, enriches the blood and nourishes the famished and exhausted nerve-cells; it does this in four minutes; it takes beef-tea twenty minutes, or, if conditions are not favorable, twice as long, and then it cannot do it half as well as the alcohol. Tea or coffee may fail altogether, but, even if coffee presents its maximum of efficiency physiologically, it is feeble when compared with the action of alcohol. Tea and coffee, by virtue of their action on the brain and cord as excitants, can only stimulate, but stimulation now is contraindicated; what is wanted is a nutritive tonic with basic sedative properties, and that is just what alcohol can furnish.

Never drink alcohol after eating; it cannot aid digestion, and what cannot aid must retard by its weight and bulk; further, it precipitates the digestive ferments, coagulates the albuminoids, and often completely arrests the digestive process. Alcohol or the malted liquors may, and often do, assist digestion when used before eating: by stimulating the gastric glands they excite healthy action in the stomach and favor assimilation. Alcohol's highest value as an aid to digestion is seen about three and a half hours after dinner if fats have formed any part of the repast. Fatty acids are then lingering in the stomach; they refuse to pass through the pyloric orifice, or, if they do, they do it so reluctantly that eructations of acid gas are belched through the mouth and nose. This condition is sometimes described as pyrosis and often occasions much inconvenience. Two ounces and a half of good whiskey, diluted with an equal quantity of water, has a value that no other agent possesses and in this instance it acts purely as a drug, for, by saponifying the fats it destroys the gases, it cleanses the stomach and aids intestinal digestion. At this time the alcohol has no toxic effect, being neutralized by the fatty acids before it can pass through the mucous membrane of the stomach.

A half a pint of whiskey or brandy taken in a draught to-day will save a life; to-morrow the same amount will destroy the life that it saved yesterday, because different conditions prevail. Alcohol destroys the walls of the stomach only after long use and when taken in a concentrated form. There is no truth in the statement so generally made that alcohol suddenly transforms an angelic man into a demon; it has no such power; it is only a revealer of character. If a man is a bad man, alcohol will make him worse; if a kind man, it will make him kinder; it seldom changes one's nature, except through the pathological processes that its long-continued use produces on the brain.

Alcohol creates nothing in the domain of mind, but it can pursue and seize a train of thought far beyond the grasp of the faculties when not excited by its action; it is the bloodhound which pursues a trail through the trackless waste, makes its circuit of the convolutions, and, in some manner not given to mortal man to know, quickens and facilitates thought. It cannot formulate and systematize this thought that it has excavated from the depths of the convolutions, as the ideas crowd so rapidly and refuse to crystallize. The line of thought which it pursues is an interrupted current with volume and intensity varying with the individual man. The senses are actively alive to the influence of alcohol and scintillate and flash, for the flame of life burns brightly and mental exaltation is high. Any surplus of alcohol taken into the system, that is not immediately burned up in the chemical laboratory of the body and transformed into some mode of motion, such as heat or force, must be injurious and act as an irritant to the stomach and as a depressant to the brain-cells. If the quantity is small this action may not be perceptible, but it is sure to increase in proportion to the quantity ingested.

The amount of alcohol to be consumed by an individual depends on the demand made on the vital forces and the resisting power of the individual; at one time it may be one dram, at another time eight ounces; it is a question of demand and supply and must not be confounded with supply and demand, something which is too often done.

Alcohol is a form of food already digested, but it is not adapted to the normal wants of the body and is only indicated at a time and under conditions which render the digestion and assimilation of other foods impossible. Alcohol has a place on the sideboard and it must have a place in the sick-room, as do opium, quinine, and digitalis, until we discover another agent more efficient and able to supplant it by virtue of its availability, and physiological action. No such agent, however, has yet been discovered (the opinions of others to the contrary notwithstanding). Not one of the drugs mentioned can take the other's place but alcohol, yet each is valuable in its own place at a given time to serve a definite purpose.

THE TREATMENT OF WHOOPING-COUGH.[1]

By HENRY COGGESHALL, M.D.,
OF NEW YORK

My paper is not properly named the treatment of whooping-cough. It is rather a suggestion for the treatment of some cases of whooping-cough, when the disease is particularly severe and in cases occurring later than in early infancy.

I had an opportunity, in 1883 and again in 1886, to observe epidemics of whooping-cough in the New York Infant Asylum. There was a large number of cases, the disease being almost universal in an institution which held more than three hundred children. The impressions I have now are that no particular treatment of the many used was of much avail and that the disease was of very painful and serious character in institu-

[1] Read before the Harvard Medical Society of New York, February 24, 1900.

tions at least. The treatment of the bronchitis, or what was called bronchitis, seemed to be of the greater importance and to that more attention was directed. There was always some remedy, new or old, for the whooping-cough itself, but after an enthusiastic start and a hopeful period there came discouragement. Jacobi now advocates belladonna in full doses, sufficient to get the physiological effect of the drug. Holt gives generous doses of antipyrin every two or three hours. About five years ago I treated a child's nose and throat for some symptoms, which I do not now remember. The mother told me afterward that it had entirely stopped his paroxysms of whooping-cough. I had not known before this that the child had the disease. In this instance the whooping-cough was in a later stage and it would be impossible to say whether the treatment put an end to such a cough as may go on for months after whooping-cough or really shortened the disease itself. That it had some effect is apparent.

Jacobi and Holt refer to treatment of the nose in whooping-cough by insufflation of powders, but neither has seen the benefits claimed.

Schadewald of Berlin, in 1881, gave the name of trigeminus cough to cough arising from what he believed to be an altered reflex irritability of branches of the trigeminus.

Sommerbrodt, in 1884, quotes Hack: "Certain signs seem to me to point to the fact that in some cases of whooping-cough the attacks may start from the nasal mucous membrane." He promises later work and makes this statement merely as a preliminary. Following the suggestion, Sommerbrodt treated a case by using the galvanocautery on the anterior ends of both lower turbinates. There was a temporary benefit, no cough for eight days and then a recurrence. The treatment was on the thirteenth day of the disease. In 1885 Schadewald said that the relation of whooping-cough to trigeminal neuroses was not determined.

Wille of Berlin, Schadewald's assistant in 1886, said: "The treatment after this supposition (that whooping-cough is due to altered reflex irritability of branches of the trigeminus) does not make it clear; sometimes improvement follows, at other times there is absolutely no result." Michael of Hamburg, in 1886, reported fifty cases treated by insufflation of various powders into the nose. He gives the preference to quinine and benzoic acid. He claims about 14 per cent. of recoveries and improvement in 80 odd per cent. of the cases. The cases are difficult to analyze. No one else, I think, found good results and the treatment appears discredited.

The treatment I have to suggest is to first cocainize as much of the nasal mucous membrane as can be done by the use of a spray, followed by cotton-tipped probes wet with the solution, then an application of a two- or a four-per-cent. solution of nitrate of silver to the nose and nasopharynx, to be followed by a mild alkaline and antiseptic wash by spray or by postnasal douching. Such treatment could hardly be carried out in infants, but with children of three years or more it is perfectly practicable. The interest is, however, to know more of the cause of the cough, when means may be found to control or modify it. The good effect of belladonna is, I think, partly due to its action on the nasal mucous membrane. I want to suggest here the use of suprarenal extract applied to the nasal mucous membrane.

Most of the efforts in treating the nose have been to destroy the germs of the disease, which I do not think to be the thing of chief importance. The four cases I have seen and treated include but one with which I could be satisfied. I mean with the stage of the disease at which it was seen, with the careful observation and record of the paroxysms, and with the result. This was in a child of six years, of very intelligent parents. Severe whooping-cough in its sixteenth day. Since four days the paroxysms have been very severe; they number thirty a day. The child vomits after each coughing-spell. After the treatment the cough ceased entirely for twenty-four hours. Then followed two to six paroxysms a day for seven days, when I treated her a second time. I would have chosen to have treated her before. After the second treatment there was not any cough for a day and a half. Four days following the second treatment I treated her a third time, after which the cough stopped. In two of the other cases the disease was in a late stage but the treatment appeared very successful. In the remaining case the disease was apparently aborted in the first two days.

CLINICAL LECTURE.

A CASE OF PNEUMOHYDROTHORAX WITH GREAT PERMANENT DISPLACEMENT OF THE HEART.[1]

By CHARLES ROSS JACKSON, M.D.,

OF NEW YORK;

ASSISTANT IN GENERAL MEDICINE AND DISEASES OF THE CHEST IN THE NEW YORK POLYCLINIC.

This young man, seventeen years of age, is much emaciated, and has an expression of long-continued suffering. His respiration is 42. There are suppurating glands at the angle of the jaw. His chest is extremely thin-walled and the respiratory movement is largely confined to the right side. Inspection shows that the cardiac apex impulse is absent from the left side, but that in the right fifth intercostal space it is present in the nipple line. Above, in the fourth and third spaces the impulse is also marked; and extends nearly to the nipple line in these spaces and to within about one quarter of an inch of the right sternal border. Furthermore, we are able to determine that the cardiac systole is 110 per minute. Men-

[1] Abstract from a clinical lecture delivered at the New York Polyclinic Medical School and Hospital.

suration shows the left side to be very slightly fuller than the right, the difference being only one-half inch at the xyphoid level.

Palpation shows that vocal fremitus is diminished or absent in all localities except in the infraclavicular and suprascapular portions of both sides, in which areas it is distinctly exaggerated. Although diminished it is easily detected elsewhere on the right side, but in a considerable area on the left side it is extremely feeble, while below, posteriorly and laterally, it is absent. The heart is located as by inspection and the systole is found to be fairly strong.

Percussion reveals a dull area corresponding to the heart as previously located. It is conical in shape, having the apex downward in the fifth space, the base upward and to the left. Dulness extends almost from the nipple line to about the right sternal border and upward to the third space. It is a larger area of absolute dulness than one finds over the normal heart in its proper location, and it is also of different shape. It must be remembered that if the heart is displaced the area of dulness will largely depend upon the extent of change in position and presenting portion of the heart. To reach this position there must be considerable rotation of the heart on its fixed tether, the inferior vena cava below and the large blood-vessels above. Bearing this in mind one must as yet reserve opinion as to whether enlargement with displacement or simple displacement, congenital or acquired, exists. Percussion further reveals considerable dulness posteriorly and anteriorly in the apex region of both lungs, bearing out the evidences of consolidation afforded by the increased vocal fremitus. Elsewhere, over the right side, the percussion note is rather high pitched and of tympanitic quality, a vesicular tympanitic or band-box resonance. On the left side, below the dull area already mentioned, a very markedly tympanitic note is heard. This tympany extends all over the left chest down to an area of absolute dulness laterally and posteriorly. This dulness below is limited and, as is demonstrable now, is altered by change of position in the patient, it is not extensive and depends, of course, upon a limited amount of fluid. The liver and spleen are found on percussion to be in their proper positions.

Auscultation shows the breath sounds at the apex of the *left* lung to be tubular; there is no vesicular element. Harsh breathing is very noticeable and is audible over a limited anterior and posterior area. Vocal resonance is here markedly increased and expiration is much prolonged. Elsewhere over the left chest no breath sounds are audible. Vocal resonance is extremely feeble in the mammary region and entirely absent below. At the right apex there is harsh breathing and prolonged, high-pitched expiration. Here one may detect an abundance of subcrepitant râles. Vocal resonance is here increased, but in other portions of the right lung is less than normal. Auscultation further continued over this lung area reveals a modified vesicular murmur with prolonged expiration. On the lateral and anterior aspect of the *left* side of the chest from the third to the fifth space a perfect metallic tinkle may be heard. This tinkle is not constant, but three or four bell-like notes are heard, then a pause, succeeded by more tinkles. Following each tinkle is a metallic resonance which is quite pronounced, a metallic echo, in fact. Of course, these tinkles and the metallic echo denote a space with hard, resonant walls and the presence of air and liquid. It is a matter of speculation as to whether the tinkle is due to a drop striking a surface of liquid or to a bubble rising through such a medium and causing the tinkle by its bursting. There are several theories advanced in addition to these two chief ones. At any rate, in this case you will notice that change from the upright to the reclining position brings out a perfect shower of tinkles. These and the metallic resonance following each form, when combined, the rarest of auscultatory phenomena. Shaking the patient with the ear to the chest brings out a splashing sound of distinctly metallic quality.

The extreme tympany and great diminution of vocal resonance and vocal fremitus with the absence of vesicular murmur below the *left* apex region proves pneumothorax on this side, and we may assume that the solidification of this lung above is due partly to collapse. Below this tympanitic area we have already proved that liquid is present. On the right side the evidence of solidification of the apex is positive, and when taken in conjunction with the subcrepitant râles points to tuberculosis. The changed vesicular murmur and the diminished vocal fremitus and resonance, together with the abnormal percussion note, vesiculotympanitic, prove the *right* lower lobes subject to vicarious emphysema.

The heart has been permanently fixed by adhesions after great displacement to the right. This displacement has been caused by a previous pleurisy, the evidence of which we still have. The heart sounds are rapid, but normal when due allowance has been made for change in position. We may regard it as free from enlargement, and may attribute its somewhat large area of absolute dulness to the displacement. The small râles in the right apex, the cough, great emaciation and suppurating glands of the neck all point to tuberculosis as the cause of the patient's condition. This is the usual factor in these cases, pneumothorax being commonly due to a perforation of the pleura by tubercular ulceration.

During the first days of observation the case showed an afternoon rise of temperature, which has since disappeared. The treatment has consisted of increasing doses of creosote and general tonics, including large doses of nux vomica, under which, with occasional attention to the cough itself by codeine or heroin, the patient's condition has improved considerably. It has not been deemed advisable to operate for the small amount of effusion, which has not increased since the first observation.

The past history of the case is of a pain in the

chest, which began about a year ago and became chronic and was followed by an attack of acute severity. It was during this period, doubtless, that the perforation occurred and pneumothorax developed. The general condition was becoming daily worse until the creosote and tonics were given, but under their use the symptoms have been ameliorated. The ultimate prognosis is, of course, most unfavorable in a case showing such marked systemic invasion and which was not treated until the disease was already advanced.

MEDICAL PROGRESS.

Prophylaxis and Treatment of Gonorrhea.—The internal use of drugs is not usually supposed to have much local effect on a gonorrhea in its acute stage, but after considerable experience J. A. O'Neill (*Med. Record,* March 24, 1900) reports most favorably upon the use of methylene blue. It is best used in gelatin capsules, in one grain doses four times per day for three or four days. In this way a cleanly and complete urethral irrigation is maintained. The urine impregnated with the blue not only thoroughly kills the germ, but also carries away all purulent discharges. Troublesome gastric symptoms may be avoided by the use of the following formula, which has been found to be most efficacious: Methylene blue, gr. i; oil of nutmeg, gtt. i; oil of sandalwood, gtt. ii. This capsule may be given three or four times daily for four days, but should then be given twice per day, and usually is not required after eight or ten days. It is also probable that methylene blue will act as a prophylactic against gonorrheal infection after dangerous intercourse.

Eructation, Regurgitation and Rumination.—Although these conditions may be associated with organic lesions of the stomach, they are usually the result of functional disturbances or are "habit neuroses," and it is this latter phase which is reviewed by H. W. Lincoln (*N. Y. Med. Jour.,* March 24, 1900). Eructation consists, at first, of the belching of gas; later, of air which has been previously swallowed. No doubt, at first, there was more or less gaseous distention, and as eructation brought relief the habit was formed. There may also be esophageal eructation, in which the air never reaches the stomach. In treatment, suggestion is all important. The patient must make every effort to suppress belching. Bromides may sometimes be of aid. Regurgitation usually comes on during the stage of digestion, especially just at the close of a meal. If it comes on later the taste varies; an hour after eating the taste is sour, due to butyric or lactic acid, or intensely sour and corroding due to hydrochloric acid, or perhaps bitter, due to peptones. It is believed by the author that atony is a prominent factor in these cases. It occurs, of course, in stagnation, cancerous conditions, etc., but the malady is usually of a nervous origin. The patient should always be forced to swallow the food again as fast as regurgitated, and to eat always in company and slowly. The diet should be arranged according to the gastric secretion and should be light and nutritious. Electricity externally and internally may do good. Small ice pellets are recommended by Alt. Rumination is more rare and may be continued for years with impunity. Heredity, custom and irritation stand preeminent as causative factors. It is a motor dynamic affection of the stomach, occurring among all classes, frequently among idiots and the insane. It is confined to the period of digestion and not accompanied by any symptoms of discomfort. The chemical condition varies from achylic to hyperchloridic. The treatment for regurgitation given above should be strictly enforced, and the patient should be warned against the contraction of the abdominal muscles. A good idea is to administer at meal-times some extremely bitter preparation, as quinine or a combination of condurango, quassia, gentian, nux vomica and capsicum. A patient usually hesitates before regurgitating this mixture a second time.

Rectal Prolapse in Children.—C. G. Cumston (*Annals of Surgery,* March, 1900) believes that one of the most important causes of prolapse of the rectum in young children is infection, causing inflammatory changes in the gut-wall with consequent loss of tone. Coughing, straining at stool, etc., then easily cause prolapse. In older individuals polypi, ulcers, piles, etc., lead to prolapse. The prolapsed portion varies in size and shape, usually shows the gut-lumen at its apex, and has a sulcus at the anal margin. It is very important to remember that peritoneum may be pulled down by the prolapsed gut, especially in front, and that small intestine may descend into this peritoneal pouch. Clinically, one cannot diagnosticate the presence of the peritoneal pouch, but must be guided by the extent of prolapse and the known anatomical relations of peritoneum to rectum. When small intestine is present in the peritoneal pouch, the anterior part of the prolapse is more prominent, the lumen at the apex points backward, and the small intestine may be reduced with a gurgle. The prolapse may be reducible, irreducible, incarcerated, or strangulated. The prognosis is never serious. Most cases, in children, yield readily to early medical treatment, a rubber rectal plug, cleanliness, and tonics. Polypus, piles, etc., should be cured. When these means fail, longitudinal cauterization through the mucous membrane often succeeds. In chronic cases, irreducible, or strangulated cases, operation must be done. Of the various operations that of Mikulicz is simplest and best. The anterior wall of the prolapse is cut through, layer by layer, peritoneum sutured if opened, bleeding points tied, and the apposed gut-ends sutured carefully together. The posterior half is then treated in precisely the same way, and the result is an end-to-end anastomosis, with very little loss

of time or blood. The suture line is covered by iodoform gauze, but no packing is used in the rectum. The dressing is removed and the rectum irrigated every day. The bowels are confined till the eighth day, and then kept regular by enemata. If the sphincter is too much relaxed a V-shaped portion may be excised posteriorly. The functional result is usually very good. Stricture seldom results, especially if the suturing has been carefully done.

Treatment of Fatty Heart.—An interesting review of the treatment of fatty heart is given by T. Schott (*Med. Record,* March 24, 1900) who, with his brother, instituted and has carried on for many years a most systematic mechanical and balneological treatment for various heart lesions, at Nauheim. He says that a fatty heart may be diagnosticated if the following conditions are detected: An easily induced dyspnea in a person having an abundant deposition of fat upon the body, especially on the chest and abdomen, with a small, feeble, frequent and easily compressed pulse, with final dilatation of the heart and diminished ictus cordis. A general plethora or fulness of the skin may also be present. He deprecates the use of diminished, or rather insufficient, food supply with the hope of decreasing the general obesity, for this must result also in interfering with the nutrition of the heart-muscle, and it is not so much a diminution in weight that is desired as a substitution of muscle for fat. The free use of mineral waters also results, as a rule, in the general debility of the system or in a temporary loss of fat which soon returns when the patient reaches home. Oertel's method of mountain-climbing has been found too severe for many cases. He advises a restricted diet, but one that is highly nutritious, thus not depending upon it for any marked reduction in weight. The gymnastic treatment, consisting of exercises with resistance, is unhesitatingly recommended for all the forms of fatty heart, since the resistance may be regulated to suit the weakest or the strongest heart. Rest should never be indulged in after eating. Massage will often prove efficient in promoting absorption of fat. The balneological treatment is very important and is also carefully regulated according to the stage of the degenerative process. Chlorosis, anemia, rheumatic or arthritic complaints, and old age, require warm temperatures. The baths usually get down to 76° F., and are increased in length up to twenty minutes. Gradually increased concentrations of salt are used in the baths and an early recourse may be had in cases of fatty heart to the effervescent running-baths.

Gout and Rheumatism.—So much unsatisfactory speculation in regard to the etiology of gout and rheumatism has been written that one reads with pleasure the interesting and suggestive article by W. H. Porter (*N. Y. Med. Jour.,* March 24, 1900) on the etiology and dietetic treatment of these conditions. Both chemicophysiological and clinical evidence point clearly to a defective oxidation on the part of the system as the chief predisposing factor in causing the pathological lesions of rheumatism and gout. This may be due to taking into the body more oxidizable food products than the normal system can fully oxidize, or a diminution in food, especially of a poor quality, may result in a malnutrition and anemia such that the food does not encounter sufficient oxygen for its perfect reduction. But why should this suboxidation result in the lactic-acid or rheumatic condition in one case and the uric-acid or gouty condition in another? Physiological chemistry teaches that the formation of lactic acid in the blood from starches and sugars is untenable. Both conditions are probably due to a suboxidation of proteid food. Uric acid is a normal excretory product not so fully oxidized as urea, always appearing in larger quantities when the nutritive changes of the body are defective. The author believes that it is manufactured in the renal cells rather than in the liver, spleen, etc., as is generally accepted. He claims that its detection in the blood is not yet by any means clearly demonstrated, and its presence in other tissues is explained by supposing a vicarious production of uric acid, resulting from the disturbed nutritive changes and the modified metabolic processes of the protoplasm of those tissues. The increased uric acid formation during digestion results from the diminution in the supply of oxygen to the renal cells at this time, which ordinarily form the more completely reduced substance, urea. Uric acid is, however, an acid product never oxidized into urea but increases in amount whenever there is an interference with the utilization of the full amount of oxygen as compared with the foodstuffs absorbed. The carbohydrates and fats require larger quantities of oxygen, but are more easily oxidized than the proteids, the latter being imperfectly reduced when too large quantities of food are taken and are excreted as uric acid. When the renal cells fail to perform their function, various tissues throughout the body assume an abnormal action and produce uric acid, which is at once changed into an urate of sodium. The oxidation of carbohydrates and fats never results in the formation of any by-products toxic to the system. It is also probable that bacteria, from their presence in the alimentary canal, are largely responsible for the production of various types of suboxidation on account of their interference with digestive processes. Thus the great factors are found to be the prolonged intake of a larger nutritive pabulum than can be perfectly oxidized, and the action of bacteria upon the proteid constituents of the food in the alimentary canal. Both carbohydrates and proteids contain all the essential elements of a food and can alone sustain life, but neither is a perfect food and a restricted mixed diet is by far the best. Animal foods are more easily digested, absorbed and assimilated than carbohydrates. On the other hand, they are more prone to produce suboxidation if not restricted in amount, since they are

nearly all absorbed. Large quantities of the vegetable food, however, are so undigestible that they are never absorbed but are passed off by the bowel. The large amounts of waste material from the vegetable food, while tending to loosen the bowels, are dangerous on account of their irritation to the mucous membrane, sometimes causing catarrhal conditions, and also on account of the fermentative changes which they are liable to induce. To secure the best results under all circumstances requires the utilization of both vegetable and animal foods, a well-regulated mixed diet in which the animal food predominates. A plain animal diet is little liable to undergo putrefactive fermentation, and, if we reduce the total quantity of food ingested so that it will never exceed the oxygenating capacity of the system, the two main factors in the production of gout and rheumatism are obviated.

Citric Acid in Ozena.—The following conclusions are drawn from a large variety of cases of ozena and atrophic rhinitis by Lewis S. Somers (*Therapeutic Gaz.,* March, 1900) on the value of citric acid in these affections. (1) The drug is of great value in preventing the fetid odor of atrophic rhinitis. (2) Its successful action depends on its direct application to the diseased tissues; for this reason all foreign material must first be removed. (3) After its use, the ozena usually remains absent from one to two days depending on the extent of the morbid process. (4) It exercises no direct action on the diseased tissues in the direction of restoration to their normal functions. (5) Unless used regularly, its action is but temporary and the ozena becomes again prominent. (6) It inhibits to a slight degree the formation of cicatrices. (7) Finally, citric acid is an important addition to the therapy of fetid rhinitis by enabling the rhinologist to combat successfully the chief complaint of the patient, namely, ozena.

Epididymitis.—This, the most dreaded of complications following or accompanying gonorrhea, is at the same time the agent of most unhappiness to the patient. H. M. Christian (*Therapeutic Gaz.,* March 15, 1900) describes a method of treatment for this condition, which is both simple and efficacious. The patient must go to bed and have the bowels moved daily by a saline laxative. A Swedish leech applied over the cord on the affected side gives great relief in the early days of the trouble. Moist heat for forty-eight hours applied continuously contributes largely to the patient's comfort. This is accomplished either by a hot-water bag or best by a flaxseed poultice entirely enveloping the testicle. After two or three days in bed, the further treatment may be begun. For those patients who, through stern necessity are kept ambulant, it becomes quite a question for the physician as to the best treatment. The old method of applying lotions of lead-water, laudanum and aconite, with the wearing of a suspensory bandage, has never appealed to the author as being efficacious. He uses an application of cotton and oiled silk, the whole dressing covered by a laced suspensory. The ointment used on the testicle is composed of ichthyol, blue ointment and belladonna ointment. Best of all is the local application of guaiacol. Great relief follows the use of this agent within twenty-four hours, even where the patient is compelled to remain on his feet. The use of guaiacol is followed by a smarting and tingling of the skin, lasting no longer than an hour. No dermatitis occurs. It is applied in the form of a twenty-per-cent. ointment in lanolin, and the testicle is first gently massaged with it and then more is applied on cotton kept in place by a suspensory or ordinary gauze bandage. The dressing is renewed every second day. After six days the following may be substituted for the guaiacol:

Ung. hydrarg.
Ung. belladonnæ.
Ichthyol.
Lanolini .....aa ℥ij

The testicle returns to its normal form in two to three weeks. In private practice it is perhaps better to use guaiacol vasogen than the ordinary guaiacol ointment.

Vaccination.—In a leading article of the *Therapeutic Gazette* for March appear some valuable hints regarding the method of vaccinating properly, which it might be well to summarize and bear in mind:

(1) Don't fail to rinse the part to be vaccinated with boiled water and dry. (2) Never apply antiseptics to the site chosen for inoculation. (3) It is best to draw no blood. A gentle oozing of the serum will give better results. (4) The vaccine must be rubbed thoroughly and persistently into the abrasion. (5) The clothing is not to be replaced until the vaccine is entirely dry. (6) Antiseptic dressings are not to be applied, except in cases in which there is danger of infection from the environment or uncleanliness of the patient. (7) The vaccine is not to be exposed to extremes of temperature. High temperatures spoil it. (8) Do not expect to find a swollen arm, indurated glands, high fever, and a suppurating ulcer—these belong to the old-fashioned means and methods of vaccinating. (9) The success or failure of the process is not to be taken for granted on the word of the patient or his parent. If there be found a typical vesicle, or the remains of one or more that may have been ruptured, the patient has been successfully vaccinated. (10) It is not always possible to pass judgment in a hurry as to whether the vaccination has "taken" or not. Sometimes the vesicles are delayed in their development.

Intra-Uterine Douches.—The danger of infecting the tissues and the danger of causing hemorrhage are the two contraindications against invading the uterine cavity during or after labor. The risk of infection is not so much due to the inability to sterilize the douche-tube or instrument as it is to the circumstances under which it may have to be introduced. In private practice the

lack of sterilizing apparatus, of sufficient assistance, and of aseptic appliances, and the situation and difficulty of sterilizing the vagina, make the practice of asepsis difficult. The risk of hemorrhage from use of the douche-tube is greatest in cases in which the uterus is empty and remains enlarged and flabby after labor. At the same time the indications for the use of the intra-uterine douche, according to Edward P. Davis (*Am. Gyn. and Obstet. Jour.*, March, 1900), are just these conditions, septic infection and hemorrhage, which are also its dangers. When there is infection in the uterus, shown by an abnormal lochial discharge, or by fever and other signs of autointoxication, the interior of the uterus should be thoroughly cleansed, as well as explored. As the finger is rarely long enough to make a thorough exploration, the writer uses a douche-curette, very carefully and gently exploring and at the same time douching the uterine cavity. There is very little pain from this procedure, an anesthetic is not needed, and the subsequent disturbance is slight. The vagina must first be made aseptic. Davis prefers to use a normal salt solution when the patient is depressed, or sterilized water. He does not believe in using solutions of mercury within the uterus, because of absorption. If further douching is desired the writer uses a douche-tube of glass, fenestrated on the side only, and with a groove running lengthwise of the tube for the return of the fluid. In post-partum hemorrhage, he does not think that a stream of hot fluid will remove the clots within the uterine sinuses. A large mass of coagulum must, however, be removed in order that the uterus may contract properly. This intra-uterine douching for hemorrhage must be followed by an intra-uterine tampon of iodoform or sterile gauze. If in uterine hemorrhage it is thought that some placenta or membranes are retained, the douche-curette should be used. When sepsis and hemorrhage are present together, the use of an anesthetic is dangerous, and the uterus must be douched and cleansed as quickly as possible. This should be done with the douche-curette and the cavity of the uterus firmly packed with gauze. Prolonged douching should be avoided and the whole procedure performed as rapidly as possible. The writer does not believe in repeated intra-uterine douches, although in a few cases a second douche seems advisable.

Soluble Silver.—Although many local antiseptics are known, it is only since the various silver compounds were introduced that the general disinfection of the body became a possibility. A. Dworetzky (*Therap. Monatshft.*, March, 1900) reviews the evolution of silver-therapy and shows how the encouraging results obtained with metallic silver in contact with germ-life soon led to experimentation with the soluble salts, itrol and actol, the high bactericidal powers of which are now sufficiently established. On attempting to inject actol it was, however, noted that a coagulation often occurred at the site of introduction, which materially interfered with absorption. Collargol, or colloid silver, the soluble, allotropic form of metallic silver, was found not to do this; in fact, it remained in solution more readily in albuminous fluids than in pure water, and salts and acids seem to have little affect on it. Applied in the form of a 15 per cent. ointment, to be rubbed into the skin, it has actually cured general acute or chronic sepsis, and locally for buboes, gonorrheal epididymitis and furunculosis, a retrogression of symptoms up to complete resolution has been obtained without surgical intervention.

External Urethrotomy.—R. Harrison (*Lancet*, March 17, 1900) considers external urethrotomy specially applicable to resilient, rapidly contractile strictures; to wounds of the urethra, either operative or accidental, where drainage is insufficient, since it is well known that clean, well-drained wounds give rise to less of the dense contractile tissue causing stricture; to stricture with urinary fistula and sinuses or with extravasation of urine; and to certain rare cases in which urethral manipulation is followed by acute symptoms of impending death, suppression of urine, rigors, etc. (*i.e.*, acute sepsis). The points of importance in the operation are: The use of a guide; the performance of internal urethrotomy as an immediate preliminary to the external operation; and the provision of free urinary and wound drainage. External urethrotomy without a guide is a difficult, dangerous, incomplete operation, and usually unnecessary. If urine can pass the stricture there must be room for an instrument if it be small enough and properly guided. The utility of preliminary internal urethrotomy is evidenced by the ease with which the external operation is performed on the grooved staff. The internal urethrotomy is done by passing a filiform into the bladder and then cutting the stricture with a Maisonneuve urethrotome. The wound must be well drained and cleansed, for the character of the tissue, by which the stricture is repaired, is materially affected by the nature and duration of the drainage and irrigation that is employed. To this point too little attention is paid.

Mild Forms of La Grippe.—Influenza is characterized, says H. Huchard (*Bull. de l'Acad. de Méd. Paris*, March 5, 1900), by a tendency to visceral congestions, asthenia of the nervous system, and diminished arterial tension. Among the mild forms there are afebrile types without any inflammation, yet with such profound influence on the nervous functions as to cause much moral, physical and intellectual depression. Or there may be a slight pulmonary congestion, almost latent, without fever, perhaps with slight cough but no expectoration, and manifested on auscultation by a few subcrepitant or crepitant râles at one or both bases. There is also a febrile type of sudden access in which the temperature may reach 104° F. within twenty-four hours

and as rapidly decline; the pulse remains at 60 to 80 and there is no appreciable organic lesion. As la grippe is one of the most powerful factors in lowering the resisting power of the body, these mild types should be recognized and the patient made to avoid contact with tuberculous or other sick people. The skin, liver, and kidneys must be kept active, the stomach and intestines being treated by alimentation rather than by drugs. The mouth and nose should be cleansed by a solution of formol, menthol, or carbolic acid. If the patient is confined to bed a milk diet is most suitable. The author considers quinine as almost a specific when used in large doses and he gives 15-25 grains of the hydrobromide of quinine a day for from one to three days, but no longer. This may be combined with an equal quantity of ext. ergot. If there is gastric intolerance the quinine may be given subcutaneously. Antipyrin is generally harmful, but may be given at the onset for headache, if combined with caffeine or black coffee. For the weakness of the nervous system use the glycerophosphates, or strychnine sulphate, gr. $^1/_{30}$, three times a day.

Tuberculosis of Stomach.—Based on an extensive pathologic experience, M. Simmonds (*Münch. med. Woch.*, March 6, 1900) concludes that gastric tuberculous ulcers are extremely rare. Although the gastric juice does not directly kill the bacilli, it renders the soil unfit for their propagation. Wherever there is achlorhydria, as in gastric cancer, the ulcers are not as rare as in otherwise normal organs. As a rule, they present small, single or multiple losses of tissue most commonly situated about the pylorus. Gastric symptoms were uniformly absent in all cases examined, thus rendering a diagnosis *intra vitam* impossible.

Pneumonia and Antipneumotoxin.—After citing some statistics as to the mortality of pneumonia, and giving a short résumé of some experiments in serum-therapy, Charles B. Canby (*Maryland Med. Jour.*, March, 1900) presents one case of pneumonia of his own and three others, in all of which antipneumotoxin was used successfully. His own patient was a youth, twenty years of age, who presented the physical signs of pneumonia with consolidation, and had a temperature of 105° F., with respirations 56 to the minute, and an uncountable pulse, at 6 P.M., when 12 c.c. of antipneumotoxin were injected. Three hours later his temperature had fallen two and one-half degrees, there was profuse perspiration, and his respirations were down to 40. The pulse was still uncountable. The next morning the temperature was 99° F., respiration 24, and pulse 96. Another 12 c.c. of antipneumotoxin were then given and from that time on his recovery was uninterrupted, and in twelve days from the last injection he was at work. In the second case reported there was a temperature of 103° F., pulse 110, rapid respiration, and the physical signs of pneumonia with consolidation. On the evening of the third day, in bed, the patient received an injection of 10 c.c. of antipneumotoxin, and the next morning he was in a profuse sweat, his temperature was 99° F., and his breathing and pulse were much improved. Four days later his temperature was normal and in eight days after the injection he was up and apparently well. The third case had pneumonia with consolidation, a temperature of 103° F., pulse 110, and respiration 80. She received an injection of 10 c.c. of antipneumotoxin in the morning. In the evening of the same day her temperature was 103° F., pulse 108, respiration 33, but on the next morning the temperature was normal, pulse 80, and respiration 20. For two days she was better and sat up in bed, but in the evening of the second day she had a chill, a temperature of 105° F., and respiration was 32. The next morning she was injected again with 10 c.c. of antipneumotoxin, her temperature being 104.2° F., pulse 113, respiration 32. In the evening there was only a slight change, but on the next morning her temperature was normal, pulse 70, and respiration 18. From this time on she progressed and in five days was well. The fourth case presented the symptoms of pneumonia, with a temperature of 103.8° F., pulse 140, respiration 42, at the time of an injection of 20 c.c. of antipneumotoxin. Six hours later his temperature was 103.6° F., pulse 102, respiration 28, and 20 c.c. more of the serum were injected. The next morning his temperature was 99° F., pulse 76, respiration 28, and the following morning his temperature was 98.4° F., pulse 70, respiration 23. From this time on his temperature remained normal and he progressed nicely.

Dysenteric Abscess of the Liver.—According to M. Kelsch and M. Nimier (*Bul. de l'Acad. de Méd.*, Paris, March 12, 1900) many cases are reported of the outbreak of liver abscesses in old dysenterics on their changing from a hot country to a temperate one during the cold season. Such abscesses are marked by their irregular course, their remissions and paroxysms, their chronicity, and their tendency to recurrence, these being the characters which distinguish the dysentery itself. The essential lesion both in liver and intestine is a necrosis. The abscess may appear first, but usually it accompanies or follows the dysentery, even appearing many years after the latter has been completely cured. The pus is yellow, bile-stained, or chocolate-colored, and is often so thick that it is missed by the exploring needle. It is mostly sterile, sometimes contains the colon bacillus, and very rarely the amœba dysenterica; but the question still remains open as to whether these organisms cause or follow the primary lesion. The pus, even when apparently sterile, can produce other abscesses which in turn contain only sterile pus. When the abscess points upward it may readily be detected by the X-rays. The authors found that of nearly five hundred cases of abscess of the liver 85 per cent. were associated with dysentery.

Pyramidon.—W. Pauli (*Centralb. f. Therap.*,

March, 1900) lauds the antipyretic and antineuralgic properties of pyramidon and finds it the best substitute for the salicylates in acute rheumatism. It may cause profuse perspiration without collapse and never irritates the alimentary canal. It is only when the functions of the system are much disturbed that undesirable symptoms are seen; thus, one anemic patient experienced painful paresthesiæ, and a second, suffering from advanced mitral insufficiency and stenosis, developed a morbilliform eruption.

Open Treatment of Fresh Fractures.—C. L. Scudder (*Bost. Med. Surg. Jour.*, March 22, 1900) drawing his material from the cases of fracture in the Massachusetts General Hospital, which were examined from one to seven years after treatment, says that in adult life 69 per cent. and in old age 100 per cent. of the results by the ordinary methods of treatment were imperfect. He classes as imperfect results those cases in which there is deformity, persistent pain, tenderness, impaired function and inability to endure prolonged use. These poor results are due to incomplete reduction, and faulty immobilization. Often satisfactory reduction is impossible because of bone-fragments, interposed shreds of soft tissue, blood, the interference of muscular contractions, or the obliquity of fracture-surfaces. Often the conditions of a fracture are such that no form of apparatus can hold the fragments in proper alignment. Since these hindrances exist in nearly every fracture, and since the percentage of imperfect results by ordinary methods of treatment is so high, it would seem to be the part of sound surgery to cut down on fractures, remove blood-clot, get good apposition and fixation of fragments, and repair as far as possible the damage to soft parts. The fear of adopting this procedure is one of the legacies of preantiseptic days. At present there is less danger in an open than in a closed fracture.

Osteomalacia.—A. Littauer (*Therap. Monatshft.*, March. 1900) mentions among early symptoms of this disease muscular weakness, nervous irritability, paresis of the iliopsoas, contractures of the adductors and increased reflexes. Later, the bending of the bones, pains on locomotion, and the peculiar duck-gait render the diagnosis easier. The disorder has been found endemic in certain localities, and, while most prevalent during the sexual life of women, any age may suffer. Rheumatic influences, a purely vegetable diet, malnutrition, and severe general disease have been considered possible etiological factors in cases not connected with gestation. In the latter the symptoms generally improve during the puerperium, but yet there is no complete natural cure. Since castration has been introduced as a remedy, many ovaries have been examined for pathological changes, but nothing in addition to a hyalin degeneration of the vessels could be discerned. Theories as to causation are plentiful, but the one assuming some deranged ovarian function to lie at the bottom of the disorder still finds greatest favor. Organotherapy has, however, proven useless except in one case reported cured after the administration of extract of bone-marrow. It is justifiable in all cases to try phosphorus before resorting to castration.

Treatment of Hydrocele.—In reviewing the treatment of hydrocele N. Cerri (*Cleveland Med. Gaz.*, March, 1900) suggests the use of a method which was first introduced by Dr. Juathrociocchi. After evacuating the fluid, a piece of catgut about eight inches long is introduced through the canula. By mechanical irritation this excites an adhesive inflammation of the serous surfaces and in a few days it becomes absorbed. If the irritation is not sufficient the catgut may be soaked in a solution of perchloride of iron before introduction. The results are extraordinary; recovery being almost certain, and, furthermore, the patient is able to attend to his business while the treatment is being carried on.

Retroperitoneal Sarcomata.—J. D. Steele (*Am. Jour. Medical Sciences*, March, 1900) says that while retroperitoneal sarcomata are comparatively rare, they deserve more attention as to diagnosis than they receive. They occur more frequently in males, and in the first, fourth, fifth and sixth decades of life, *i.e.*, later than sarcoma ordinarily occurs. Traumatism plays little part. It is a very rapid-growing tumor, the average duration being about nine months. It arises most frequently in the lumbar region. When lateral it is most frequently on the right side. It is usually lobulated and capsulated, hard and firm in its early stages, very prone to degeneration later, of a hemorrhagic, puriform or myxomatous type. In about a third of the cases it becomes cystic. Metastatis, while uncommon, is most apt to occur in the liver and lungs. The softened mass may rupture into the intestine or peritoneal cavity. The onset is insidious, the first symptom being usually functional digestive disturbances, and then pain and edema in the lower extremities due to pressure effects. Later there appear cachexia and symptoms due to pressure on the abdominal organs. At first the physical examination tells little. Later the colon is pushed forward and lies on the tumor's anterior surface. In lateral growths the small intestine is pushed to the opposite side, while median tumors are surrounded by an irregular circle of small intestine. This arrangement of bowel is very characteristic of all retroperitoneal growths. The tumor may fluctuate, and may move either with respiration or on palpation. Diagnosis, beyond determining the retroperitoneal and malignant character of the growth, is very difficult, especially the differentiation from tumors of the kidney or suprarenal body. Exploratory incision alone determines surely the position and character of tumor. Early surgical interference offers the only hope of cure.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

SATURDAY, MARCH 31, 1900.

FUNCTIONAL AND ABORTIVE MYXEDEMA.

THE realization that certain special forms of constitutional disease do not always occur in their complete and typical forms, but that they may exist with such slight symptoms as to require careful observation for their detection, is one of the most interesting phases of advance in medical diagnosis during recent years. Mild forms of so-called exophthalmic goiter are, however, very frequently encountered, and the connection between these abortive types, presenting only slight tachycardia, some tremor and digestive disturbances, are now recognized as partaking of the nature of the severe types of the disease originally described by Basedow. Raynaud's disease, in its mild form, is, by no means, the rare malady that symmetrical gangrene has very happily always been. The suggestive relationship between all of the disturbances of peripheral circulation, from Weir Mitchell's disease, erythromelalgia, up to the complete cessation of blood-flow that causes gangrene, is now very generally recognized.

Recent observers, especially in France, have called attention to the fact that abortive forms of myxedema, analogous to the mild types of Raynaud's and Basedow's disease, are not infrequent. The patients are apt to be undersized and usually have attained, late in life, their growth and development, their teeth and the use of their limbs; although they may have been apparently normal but delicate children. They early take on the appearance of being much older than they are. In the milder forms no true myxedema occurs, that is no mucinoid infiltration of the subcutaneous areolar tissue, but the mucous membranes are usually extremely liable to functional swelling and even to localized hypertrophy. The mucous membrane of the nose is easily affected by irritants, microbic or mechanical, or by unfavorable meteorological conditions. The tonsils are often hypertrophied and there is prone to be a ring of abnormally enlarged adenoid tissue in the pharynx. The teeth decay early and the hair falls out prematurely. The falling of the hair of the outer part of the eyebrow is said to be almost pathognomonic of this *myxedeme fruste*, or hypothyroidia, as the French writers call it.

Women who suffer from the affection are prone to have disturbances of the circulation of their mucous membranes at the time of menstruation. A tendency to hypersensitiveness of nose and throat and even of the vaginal mucous membrane has often been noted. Such patients frequently suffer from chronic constipation which seems to be due to the disturbance of the circulation of intestinal mucous membranes. Painful conditions of the joints are often noted and have usually been treated as rheumatism. The malnutrition, arthritic nerve-endings incident to the lack of certain products of the thyroid gland in the circulation, is supposed to be the cause. When hypothyroidia exists women endure very badly the strain of frequent childbearing or of prolonged lactation.

Where the symptoms noted are really due to a defect of the thyroid, even although it may be impossible to recognize that fact by palpation, the administration of extract of thyroid in small quantities brings relief, and restores normal metabolism. The recognition of the cause of these easily misjudged symptoms is, however, most important. Patients with tendencies to the development of symptoms because of defective thyroid secretion may be warned of their inability to withstand the serious crises of existence and be taught the limits of their capacity for the "strenuous life" that has become the passion of the day.

THE ART OF MEDICINE.

WHEN one considers by what a painfully slow process medicine has emerged from the Cimme-

rian darkness of mysticism and empiricism, and wormed its tedious way into the borderland of exact science, there is little cause for wonder at the present trend of medical research toward the ultrascientific. We are ashamed—and pardonably so—of our long lineage of leeches and barber-surgeons, of Sangredos and Purgons, and are naturally enraged at being hampered in our progress by their modern counterparts—the motley throng of pseudoscientists, healers, osteopaths and other leg-pullers *"ad infinitum"*—who pullulate in every nook and corner of the country. And yet, are we not in a measure to blame for the existence of these flourishing hordes, by exalting the *science* to the unspeakable detriment of the *art* of medicine?

In medicine we believe that the ancient aphorism about the exception proving the rule does not obtain. It follows, then, that mankind can not be dealt with medically from any hard and fast scientific standpoint. The constant surprises with which we daily meet in our observations of the varying reaction of different organisms to identical morbific agents, and the blank failures which so often attend attempts at infant feeding by the scientific modification of cow's milk, sufficiently attest the truth of this belief.

Consider how often Nature—with supreme indifference to the inductions of our subtlest logic based upon scientific research—plays havoc with our *"ex cathedra"* prognostications. That this fact was keenly appreciated by that prince of medical wits, Dr. Holmes, is evidenced by the following lines from his poem, "The Morning Visit"—a bit of medical wisdom that should jingle in the brain of every young M.D. who leaves our schools:

> But Nature's graduate when she schools to please,
> Wins back more sufferers with her voice and smile
> Then all the trumpery in the druggist's pile.

Is it any wonder that that ineffably wretched victim of a bedeviled nervous system, the neurasthenic—a creature whose nervous energy is often at so low an ebb that he marvels at the existence of people with sufficient strength to walk about or even to maintain themselves erect—should turn with disappointment, rage even, from the offensively healthy and eupeptic doctor who assures him—with a fine scorn at his childish absurdities about his health—that he is "all right if he would only think so," and look for comfort and succor to the crafty quack who stands ready to cure his "heart disease" or his "paralysis?" We may sneer at such charlatanry and, from the lofty pinnacle of science, contend that the patient thus relieved of his infirmities is a gullible fool; but, for the most part, the physician has to deal with sick, and, therefore, miserably illogical—from our viewpoint—specimens of humanity, and not with scientists and profound reasoners.

To draw the line at charlatanry in medicine is not so extremely easy as commonly supposed. The superiority of the educated doctor over the quack lies in his knowledge of morbid processes and in his diagnostic skill, but these very accomplishments must surely bring him to grief if, guided blindly by them, he neglects any means whatsoever to give his patient both hope and relief. The merest tyro in medicine soon learns—and without the aid of any profound psychological treatise—to recognize the immense influence of mind over matter, and he would be little short of an idiot if he did not incorporate into his therapeutic armamentarium that powerful agent, suggestion—the main tool of the charlatan.

There are so many factors of importance (not in the scientific treatises) for the successful treatment of the sick that lack of space does not permit the enumeration of all, but two seem so salient and, in a way, so amusing that they are worthy of note. These are the physician's personality and appearance. Imagine, if you can, a person with the sensibilities of a pachyderm attaining eminent success in the treatment of nervous invalids, or one with an incoercible acne rosacea in the rôle of a dermatologist *"qui est dans l' train,"* as the French say.

We should never forget that Nature is kind even when she appears most cruel. Witness the subtle toxin she generates in the consumptive, which makes him hopeful to the very end. Surely hopefulness is the inalienable right of every sufferer, and we should strive most zealously to foster it by every canon of medical art rather than to shatter it by the inexorable arguments of science. Think what the world would have lost in the way of art and literature had certain of the masters, victims of incurable disease, not been buoyed up by the optimism of wise medical counselors and thus enabled to forget, in their work, the fatality of their maladies. The letters of that enchanter of two worlds, Robert Louis Stevenson, make goodly reading for medical men of pessimistic tendencies, in that they show what prodigies of both mental and physical labor were accomplished, and what a cheerful frame of

mind was preserved in the face of a disease which rendered its victim the frailest of the frail.

To sum up in a word the lesson we would teach, we should never allow ourselves to be so hampered by a purblind adherence to what we are pleased to call the hard facts of science that we neglect in the alleviation of the sick the simple, and often homely, measures suggested by art.

ECHOES AND NEWS.

NEW YORK.

Fire in Erie County Hospital.—A fire at midnight burned out the interior of the consumptive ward of the Erie County Hospital. Fortunately, all the sixty patients were carried from the building without injury.

Public School Baths.—Public School No. 1 of Manhattan Borough is to be provided with twenty-six needle baths, with hot and cold water. These will be open for the use of the boys of the school. The plan is to allow the boys, under the direction of the principal, to bathe in rotation by classes.

Smallpox at Columbia.—A law student of Columbia University, living in West One Hundred and Twenty-first street, was discovered last week to be suffering from smallpox. He was promptly removed to the hospital for contagious diseases, and four hundred of the students were vaccinated.

Smallpox at Quarantine.—The freighter "Pawnee" arrived in New York harbor on March 20th, from Mediterranean ports, by the way of Bermuda, with three cases of smallpox on board. She was quarantined and all her crew, save the three affected, were transferred to Hoffman Island for observation. These three were taken to North Brothers Island.

A Destitute Physician.—Dr. Charles Obermüller of 144 East Thirty-third street was taken to Bellevue Hospital, on March 23d, destitute and suffering from alcoholism. He was graduated from Bellevue in 1888 and afterward had charge of the Outdoor Poor Dispensary. Then he became a lecturer in the college and later was chief physician of the Pennsylvania Railroad. Three years ago he began to drink heavily.

Contagious Diseases.—For the week ending March 24, 1900: Measles, 828 cases, and 34 deaths; diphtheria, 265 cases and 46 deaths; laryngeal diphtheria (croup), 26 cases and 13 deaths; scarlet fever, 176 cases and 10 deaths; smallpox, 2 cases; chicken-pox, 26 cases; tuberculosis, 251 cases and 192 deaths; typhoid fever, 27 cases and 8 deaths; cerebrospinal meningitis, 8 deaths. Totals, 1601 cases and 311 deaths.

Doctor's Bespattered Overcoat.—Dr. Henry Spitzer secured in court a judgment for $27 against a builder for damages sustained through the latter's workmen having spattered some mortar on his clothes while he was passing a building under construction. For an hour lost in cleaning his coat the doctor demanded fifteen dollars contingent damages. This was not allowed nor would his demand for $40 be allowed, although the doctor declared his clothes were worth that sum.

Fruit Sale for Floating Hospital.—A few years ago a car-load of oranges was donated by some Californian fruit-growers to the "Los Angeles Home for Indigent Children." This fruit was sent to New York City for auction. Over two thousand dollars were realized. The Southern California Fruit Exchange of Los Angeles has recently donated a car-load of the best California navel oranges for the benefit of the sick children of the poor of New York, and has selected St. John's Guild as the medium through which the proceeds shall be expended.

Changes at St. Luke's Hospital.—On March 26th the Rev. Dr. George S. Baker, Superintendent of St. Luke's Hospital, was retired by the Board of Managers and appointed Pastor Emeritus, at a salary of $2000 per year. Dr. Baker has served the hospital for nearly a quarter of a century. The resignation of Mrs. Quintard, who was the Directress of Nurses until she left for work in Cuba, a month ago, was accepted. It was rumored that there had been dissatisfaction with Mrs. Quintard's work as head nurse in that she showed favoritism toward the Canadian contingent among her nurses, but both Mr. Miller and Dr. Baker declared that all such rumors were without foundation. The hospital staff has been enlarged by the creating of a pathological interneship. This member of the staff will be an assistant in pathology after the manner established by Dr. Thacher at the Presbyterian Hospital.

PHILADELPHIA.

Hospital Donations.—The proceeds of the annual Charity Ball have been awarded, each of the following institutions receiving $3000: University of Pennsylvania Hospital, Jefferson College Hospital, Southeastern Dispensary for Women and Children, and the Women's Directory.

Quarantine Cards.—A Committee of the County Medical Society, consisting of Drs. Tyson, Meigs and S. Weir Mitchell, has presented to the Mayor a resolution of the Society asking that the present plan of posting cards on houses containing cases of contagious disease be modified or discontinued. People object to these signs and are led to deceive the authorities.

Hospital Fire.—An explosion near the Jefferson Hospital March 22nd broke all the windows in one end of the building and finally set fire to it. The patients were all removed to the College building and to other hospitals without mishap, the nurses and hospital staff exhibiting

admirable courage and discipline. The damage to the hospital was slight.

Mutter Lectures.—Dr. John B. Roberts of the Polyclinic Hospital will deliver the Mütter lectures on surgical pathology for the year 1900. The course consists of ten lectures, beginning March 27. The subject is "The Surgical Treatment of Congenital and Pathological Disfigurements of the Face."

Health Report.—Deaths for the week ending March 24th were 637, an increase of 57 over those of the previous week and an increase of 106 as compared with the corresponding week of last year. Contagious diseases: Diphtheria, 72 cases, 21 deaths; scarlet fever, 75 cases, 3 deaths; typhoid fever, 75 cases, 13 deaths.

College of Physicians.—At the meeting of the Section on Ophthalmology, March 20th, three cases of partial restoration of sight by operation after periods of blindness of respectively thirteen, thirty-three and sixty years were reported. Stress was laid upon the fact that operations to relieve traumatic blindness were most successful when the eye had reached a quiescent state.

Dr. Shoemaker stated that enophthalmos may be due to atrophy or paralysis of the cheek ligaments disturbing the balance of power. Tenon's capsule and the cheek ligaments are more involved in that condition than is Müller's muscle.

Dr. G. E. De Schweinitz filled a collapsed eyeball, caused by a refractory patient during a cataract extraction, with physiological salt solution, and obtained excellent results. The upper half of the iris had been torn from the margin and was lying in the bottom of the anterior chamber. This was brought up and when the eyeball was filled it appeared as in an ordinary cataract operation. At the end of seven weeks vision was twenty-fiftieths.

Pathological Society.—At the meeting of March 22nd Dr. J. A. Scott reported a case of hemorrhagic pancreatitis. The symptoms resembled those of acute intestinal obstruction and the patient died on the operating-table. There had been severe epigastric pain for three days, accompanied by vomiting, the pain finally being transferred to the left iliac fossa. There was no jaundice. Areas of fat-necrosis were found in the mesentery and omentum. Changes in the endothelium of the pancreatic vessels were found and many of them contained thrombi. Dr. Simon Flexner stated that the vessel changes consisted mainly of a proliferation of the endothelial cells, whether this was primary or secondary not being clear. The thrombi he considers as an accompaniment of the changes rather than as the cause, for the reason that they are found in the vessels of the dead area of the organ. The distribution of the areas of fat-necrosis in the omentum and mesentery along the line of the vessels corresponds to experimental cases which he has produced. This is also true of the areas of thrombosis.

Dr. J. F. Schamberg cited a case of tuberculosis of the skin of the hand from accidental inoculation. The patient was a laryngologist who had been treating two tuberculous cases.

CHICAGO.

Gift to Evanston Hospital.—Mrs. Herman D. Cable has made known her intention of presenting to the Evanston Hospital a gift of $50,000 prior to her departure for Europe. Half of this amount is to be used in the erection of the Herman D. Cable Memorial Building, and the other $25,000 is to be devoted to the maintenance of a children's ward therein, which will be known as the Anita Hutchins Cable Ward—a memorial to the donor's daughter. Mrs. Cable's munificent action has led to the formation of a plan by President Elliot and others interested in the Hospital for the establishment of a permanent endowment fund for the institution.

Smallpox Increasing.—Chief Clerk Pritchard of the Chicago Health Department has made a tabulated list of smallpox cases throughout the various States, which shows a large increase in the United States for the last week ended March 10th, of 1272. The figures for the week ending March 16th in thirty-six States and Territories show 3952 cases. The State showing the largest number of cases is Louisiana, with 2015 cases, and Texas comes next with 517. California is the State least affected, having but 3 cases. New York has 11 cases, as against 74 for Illinois. Five of these 74 have been discovered in Chicago.

Election of Officers.—At a meeting of the Board of Directors of the Chicago Eye, Ear, Nose and Throat College, recently held, Dr. A. G. Wippern was elected Vice-President and Dr. Wm. L. Ballenger was reelected to the Chair of Otology, Laryngology and Rhinology.

Mary Thompson Hospital.—The annual meeting of the directors of the Mary Thompson Hospital for Women and Children was held March 20th. The annual report showed that 517 patients were admitted during the year, and the total receipts were $20,744, leaving a balance of $300. The sum of $10,000, bequeathed by the late George M. Pullman, was formally accepted.

Chicago Drainage Canal Board.—The Engineering Committee of the Board has received a report on the examinations of Illinois River water, carried on in the interests of the Board. The report states: "The condition of the water at the mouth of the Illinois was almost normal with that of the general water supplies of the main tributaries of the Illinois River. The investigation so far shows clearly that there has been scarcely any pollution of water supplied to St. Louis at the intake."

Mortality Statistics.—Of the 547 deaths reported to the City Health Department last week, ending March 17th, 116 were due to pneumonia. The death-rate is 21 in excess of that of the pre-

ceding week, but the Department claims a gratifying decrease in mortality from the group of preventable diseases, particularly from diphtheria and scarlet fever. It is also shown that the excess in the total deaths is found among chronic invalids of advanced age, upon whom the remarkable March weather has had disastrous effects. As a result the number of deaths among those more than sixty years of age was higher last week than ever before recorded by the Department for a like period—44 of the total 547. The principal causes of death among these were the acute pulmonary affections, pneumonia, bronchitis, diseases of the heart and of the kidneys.

Medical Inspection of Schools.—Mr. W. Lester Bodine, Superintendent of Compulsory Education, has submitted his report to the Board of Education on medical inspection from February 19th to March 16th. The report shows there were 21,404 examinations during this period. As a result of them, 1213 pupils were excluded because of contagious diseases. The reports of the individual medical inspectors show that the number of cases of mumps has increased largely, while there are fewer scarlet fever and diphtheria cases. Since January 8th there have been 54,000 medical inspections, and 3444 pupils excluded. Mr. Bodine believes the great good which results from medical inspection is rapidly becoming apparent. Words of praise are heard on all sides for the Board of Education in establishing the medical inspection.

Appointments at Rush Medical College.—Dr. Henry B. Favill will be Professor of Therapeutics and Preventive Medicine. Dr. Daniel R. Brower, who formerly occupied the Chair of Meteria Medica, Pharmacy and Therapeutics, and Dr. John M. Dodson, of the Chair of Physiology, will in the future have special departments connected with the Chair of Medicine, now under the direction of Dr. Frank Billings, jointly shared with Dr. James B. Herrick and Dr. Henry M. Lyman. Dr. J. Loeb of the University of Chicago will be the successor of Dr. Dodson as Professor of Physiology. It is said that much of the work of the junior class will in the future be done at the University of Chicago. Other changes in the Faculty are under consideration. Dr. Frank Billings has been selected Dean.

Intestinal Anastomosis.—At a meeting of the Chicago Gynecological Society, held March 21st, Dr. Alexander Hugh Ferguson showed a clamp and enterotome, a modification of Grant's enterotome, which he uses as an aid in suturing. The bowel clamps are applied to the bowel on either side of the field of operation for the purpose of preventing the escape of intestinal contents while operating. They are composed of two blades, one of which is fenestrated, and both are covered with rubber, so that the pressure does not come directly on the bowel between the blades, but on the rubber itself. This pressure is controlled by two screws, one at each end, which can be regulated to a certainty. The instrument is employed in extra-intestinal methods of suturing in end-to-end, lateral, or end-to-side anastomosis, as an aid while doing the sewing. It is easily and rapidly applied; it minimizes the chances of soiling the peritoneum with intestinal contents; it holds the bowels firmly and securely together, so that the most accurate stitches can be quickly applied, thus greatly lessening the liability of leakage. It aids in completing the operation except the small hole through which the blades of the clamp entered; the stitches are inserted first, the intestinal walls cut afterward, and the pressure of the clamp on the blood-vessels of the mucous membrane for several minutes while sewing is being done lessens the tendency to hemorrhage. The new passage made between the bowels may be of any size necessary, thus preventing the possibility of stricture formation.

GENERAL.

Dr. Osler Declines.—Professor Osler, who was being considered by the authorities of Edinburgh University with reference to appointment to the Chair of Medicine in that institution, says that he is not a candidate.

Gift to a Boston Hospital.—The Massachusetts General Hospital received, on March 24th, a gift of $75,000 from an unnamed donor. A condition is that the same amount be raised in addition. The whole is to be used for a new out-patient department.

Smallpox at Yale.—Upon the occurrence of a case of smallpox at Yale University, Professor Hadley advised all the students to be vaccinated, saying: "This is the right remedy and the sure one; the wrong remedy is to run away. If you have not the disease in your system vaccination will make you safe."

Mortality in the Army in the Philippines.—The official records of the War Department show that from June 1, 1898, the date of the occupation of the Philippines, to February 17, 1900, the mortality has been 65 officers and 1460 men, a total of 1525. Of these 612 were due to casualties sustained in battle and the balance to disease.

Army Diet-Kitchens.—The death of Mrs. Anne Wittenmyer, who died recently at Saratoga, N. Y., recalls the fact that she was the practical organizer of the army diet-kitchens. It was while in the hospitals at Chattanooga in the winter of 1863-64 that she organized the system for supplying food for men whose condition was the most serious. The Government furnished the staple articles and the Christian Commission and Soldiers' Aid Societies provided the delicacies and the nurses to superintend the diet-kitchens in which the food was prepared.

Dr. Seaman's Prize.—Dr. Louis L. Seaman, late Major Surgeon First United States Volunteer Engineers, presented to the Military Science Institution some time ago $100 in gold (or a medal

of that value, as the successful competitor might elect) for the best thesis on the subject of "The Ideal Ration for an Army in the Tropics." The papers were submitted to a board of award and on March 27th the prize was unanimously awarded to Captain E. L. Munson, Assistant Surgeon, United States Army.

Hospital Ship "Inquiry."—The recent report on the hospital ship "Missouri," made by Colonel Long, has not been satisfactory to Secretary Root, who has appointed a Board of Investigation, one of the three members of which is Major Surgeon Henry S. Kilbourne. The "Missouri" left New York several months ago after being completely fitted out as a hospital ship. She was in charge of Major Arthur, an army surgeon, and there was constant friction on the voyage between him and Captain Dillon, the ship's master.

London's Water Supply.—The Royal Commission on the Metropolitan Water Supply is now considering definite plans for the future water service of London. A constant supply of water, the Commissioners point out, is not at present given to all the houses in London; about 72,000 are supplied only intermittently. Regarding the amount of water which will be necessary in the future, provision is being made for the requirements reaching forward to the year 1941. The amount of water required per head is reckoned at 35 gallons per day, or a total of 425,000,000 gallons. The estimated population in 1941 is placed at 12,000,000 of people. Provision will also be made to supply water to the upper stories of the lofty buildings.

Appeal to Bird-Lovers.—The American Ornithologist Union appeals to every bird-lover to assist in protecting the breeding-places of sea birds. This country is on the verge of losing forever one of the main features of its seacoast charms—the sea-birds themselves. In fact, the terns, the most exquisite of the gull family, and which formerly thronged our whole coast, have been so nearly wiped out by agents of the milliners that this year's onslaught, already fully organized, will glean almost the last pair from the few small breeding-colonies which remain, wherever these are unprotected. And the larger gulls, which are not only very beautiful, but absolutely essential as harbor scavengers, are also being decimated for the same purpose. In addition to the esthetic considerations the protection of these birds as scavengers is an important consideration tion.

Divided Disciples.—We learn form the *Vegetarian Magazine* that the disciples of vegetable food are divided into two schools, between which the dividing line is the earth's surface. One school sanctions all vegetables, the other only such as grow above the surface of the earth, except asparagus, which grows partly above the earth, and which, we suppose, is too good to lose. This latter school forbids the potato because it is too earthy. The following argument by a "woman physician" covering this vegetable is considered conclusive: "Never yet have I known a man or woman whose diet showed a preference for potatoes and other underground starch products who didn't likewise show a heaviness of mind and body. He steps weightily, he thinks slowly, his speech is halting, if not most of the time punctuated by a full stop. I know of no intellectual handicap like potatoes. On the other hand, I can always spot him who lives chiefly upon the succulent above-ground plants. Like them he is light, airy, quick in all his motions, ready with his tongue and never found wanting in his thoughts."

CORRESPONDENCE.

NAUHEIM AS A SUPPLEMENT TO CARLSBAD.

To the Editor of the Medical News:

Dear Sir:—Allow me the privilege of your columns to take exception to a statement made by Dr. Manges in his contribution to the discussion on diseases of the heart before the New York Academy of Medicine, published in your issue of March 10th. The statement referred to and the sentence after it are as follows: "From Carlsbad the physicians are now accustomed to send patients who have taken the reduction cure to Nauheim for after-treatment. It is no wonder that this is so, for rapid loss of flesh always means loss of tone in all muscles, especially the heart muscle." The statement contained in the first sentence, involving, at it does, a rigorous regimen and treatment as indicated in the sentence following, should, to have the weight it deserves, if true, and apparently intended, be substantiated by the quotation of statistics, or, at least, of a sufficient number of cases to make it of practical value. The feasibility of collecting such statistics appears when we consider the thousands of visitors who frequent both health resorts referred to and the number of capable and reliable medical men there resident. Having spent four weeks in Nauheim last summer, I venture to give the result of such information on this matter as I was enabled to gather.

Being at the time practically at leisure, I made it my business to inform myself as thoroughly as circumstances would allow regarding Nauheim methods of treatment and the frequenters of its baths. Of course, my attention was not specifically directed toward learning how many visitors came or were sent from Carlsbad, after taking the cure there. Now, considering that during the Carlsbad season, extending from the middle of June to the middle of August, it harbors over 20,000 visitors, and Nauheim from the middle of May to the end of September over 10,000 visitors, a fair percentage of both classes being Americans, it is significant, although I repeat my inquiries were not specifically directed to the subject, that I was never informed that Nauheim physicians were wont to have Carlsbad patients referred to them or that Carlsbad patients, after completing their cure, were wont to resort to Nauheim on

account of impairment of heart function. If a migration from Carlsbad to Nauheim had become "customary," would it not be current knowledge, obtainable without specific inquiry?

My chief reason for challenging Dr. Manges' quoted statement is that it reflects, evidently without intention, unfavorably on our Continental colleagues. It implies an indifference to their patients' greatest good, entirely inconsonant with their well-known unselfish conscientiousness. It is rendered improbable when we consider how persons select their respective baths. About to visit a "Kurort," the patient consults his family physician or an authority of his native or the nearest university town, as to the appropriate one. He is subjected to careful examination and receives his directions. Arrived at the "Kurort," the patient places himself under the care of a "Badearzt," who supervises his "cure." By him he is again subjected to examination. The cure at Carlsbad is known to the laity even to be a trying one, from which individuals with weak constitutions are barred. Is a physician, then, likely to ignore this fact in the case of a patient with a weak heart Is the "Badearzt" likely to allow a person to undergo a reduction cure whom he finds suffering from symptoms (not difficult to recognize) of an incompetent heart? The professed object of the cure being to add tonicity to the heart-muscle while superfluous fat is gotten rid of, no patient would be allowed to take the cure in such a manner as to weaken that organ.

But supposing, for argument's sake that the heart-muscle has been weakened. The "Badearzt," in recommending a resort for after-cure, would more probably place his patient under the invigorating influence of a "Luftkurort," as, in fact, I am informed, is generally done, than to subject him to the further initial depressing effect of the Nauheim cure and climate. For physicians at Nauheim, generally, admit that the primary effect of the baths are depressing, and, in consequence, insist on having trained and experienced attendants accompany their patients during the first few baths. Evidently Dr. Manges has reference to this primary depressing effect when he states further on in his paper: "Such . . . serious disturbance of a compensation which might otherwise have kept the patient in reasonably good condition for years. . . . has even occurred at Nauheim itself and patients have been worse on their return from a voyage that they hoped would be a source of the greatest good."

Charles Schram, M.D.

1074 Madison Avenue, New York,
March 12, 1900.

Insanity Expert Insane.—Dr. Richard S. Dewey, who was formerly head of the Kankakee Insane Asylum and recently in charge of a sanatorium at Wauwatosa, Wis., is insane and under restraint. Dr. Dewey originated the cottage system, under which insane patients were divided into different classes.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, March 17, 1900.

ALLEGED DEFECTS IN HOSPITAL SERVICE AT THE CAPE—WOUNDS NOT DRESSED FOR THREE DAYS—OFFICIAL UNWILLINGNESS TO USE VOLUNTEER NURSES—GENEROUS RESPONSE OF NURSES AND DOCTORS AT LADYSMITH—AN ASTONISHINGLY "TRAVELED" BULLET—REGRETS AT THE RETURN OF SIR WILLIAM MAC CORMAC AND MR. TREVES—ROYALTY AND REFORM—THE PHOSPHORUS COMMISSION.

Two of the colonial newspapers, one at Cape Town and one at Pietermaritzburg, have made charges of negligence and inadequate equipment against one or more of the base-hospitals at these two places. The charges are very similar in both cases, that wounds are left undressed for days, that nurses are too few, and that there are both shortage and red-tape difficulties in the availability of hospital-supplies. That there is nothing vitally serious in the charges is easily seen by their investigation and almost complete refutation in person by Sir William MacCormac and Sir William Stokes respectively, but that there was a slender basis for them of a curiously mixed character seems to be more than half admitted. The shortage in the Army Medical Corps, so striking in the case of the medical officers, extends to the rank and file, and medical correspondents frankly state that at the Cape Town Hospital the staff of attendants is seriously overworked, and that certain wards are in consequence practically without attendance after 5 P.M., in spite of the fact that the attendants average only three nights in bed each week. And yet the Department is said to be refusing the services of scores of volunteer nurses, both trained and untrained, on the ground that it can not provide proper accommodations for them, and also, apparently, for fear that their presence in a military hospital will in some way imperil the preservation of that sacred fetish of officialdom, discipline. What happens when the military authorities abandon this attitude of aloofness from volunteer assistance has been well shown at Ladysmith, when, upon the raising of the siege, a single telegram from the principal medical officer, asking civilian physicians and nurses in Durban and Pietermaritzburg to volunteer for immediate service there to relieve the fearfully overworked staff, was responded to at once by nearly double the number of offers of service that could be made use of.

Part, however, of the charges against the hospitals made by *The Times of Natal* appears curiously enough, to be based upon a misunderstanding of modern methods of wound-treatment. Because a wound has not been dressed for three, four or five days, even although it be dry and free from either discharge or pain, or "covered by a patch of dried and clotted blood," the pitying reporter is sure there is shameful neglect

somewhere and rushes into print accordingly, not realizing that the perfection of aseptic wound-treatment lies in the extent to which it can let well enough alone and not interfere with the first dressing, even although this has been applied in the field, so long as the wound is doing well under it.

An extraordinary case of "traveled" bullet is just reported from Northampton as one of the casualties of the last Transvaal war: A trooper was wounded at Majuba Hill, in the upper part of the chest near the shoulder, and, as the bullet could not be located, it was left in the tissues. A few days ago the man noticed a lump in his thigh and on seeking advice the bullet could be plainly felt and was accordingly taken out just below the hip-joint. This, if correctly reported, must be added to the "echoes of Majuba Hill" of which we have heard so much.

The nearly simultaneous return of both Mr. Treves and Sir William MacCormac from South Africa is causing general regretful comment, as it robs the consultant staff at the front of by far its two most distinguished members. Especially is this regret felt in Sir William MacCormac's case, as it is feared that the fatigues of active campaigning have proved too much for his strength at his comparatively advanced time of life, and that he is returning largely upon that account. Mr. Treves' health has also suffered from attacks of the prevailing dysentery, but he is reported as practically recovered, and his return seems to be due to important engagements which were announced some time ago as necessitating his return in March. At all events, both these gentlemen can have the satisfaction of feeling that they have borne the brunt of the heaviest work and organizing of the medical part of the campaign, and that probably the result now is only a question of time and a comparatively short time at that.

The advantages of royalty as a figurehead in various reforms was strikingly shown last week in the admirable speech of the Prince of Wales at the opening of the splendid model buildings and dwellings, built by the London County Council in one of the worst slums of the East End—Boundary Road. His Royal Highness' presidency of the Association for the Prevention of Consumption and of the Hospital Fund which bears his name may possibly be set down as matters of form and the duties of his high position, but in this instance his presence was due to a genuine personal interest in and practical experience with the problems involved. Not only has he been an active member of at least one Royal Commission on Housing, but he was one of the earliest shareholders in the schemes for the erection of model dwellings which have borne such magnificent fruit in London of late years, and he has built model cottages for the farm-laborers upon his estate at Sandringham. So that his cordial endorsement of the vigorous action of the County Council in these directions comes with double force and is expected to much stimulate both Parliament and the Government to drastically improve upon the very imperfect bill already commented upon, which is now before them. He especially urges the necessity of having the responsibility for the insanitary condition of dwellings brought home definitely to some one person or party who may then be dealt with accordingly, as under the present complicated condition of English property tenures it is often impossible to find out who is responsible for a given building. The Prince himself has had practical experience with the difficulty in his determined attempts to reform the condition of his own property in Lambert, which he has so far found impossible on account of the long leases and complicated system of subletting which prevent his fixing the blame definitely upon any one or even calling them to account if he could do so. To this end he advocates compulsory registration of owners of all such properties and far less generous treatment of them in condemnation and clearance schemes, the present enormous expense of which actually puts money in the pockets of the guilty parties.

The Government Commission upon the Prevention of Phosphorus Neurosis is making excellent progress during its present session and sustaining the excellent regulations proposed by the Home Office as to mutilation, cleanliness, and the regular supervision of the work-people by competent dental experts against the protests of the manufacturers. Many of the latter, it is also gratifying to note, are announcing the accomplished or prospective adoption of processes which will do away with the use of yellow phosphorus altogether in the greater part of the work, but, unfortunately, they are making these amendments the ground of an opposition to the new regulations as being superfluous. We fear that under the circumstances their "improved processes" must be looked upon with suspicion for the present.

TRANSACTIONS OF FOREIGN SOCIETIES.

British.

RESPIRATORY JACKET FOR EMPYEMA—UNUSUAL SYMPTOMS OF RHEUMATISM IN A CHILD—HEMOTHORAX OF UNEXPLAINED ORIGIN—SUCCESSFUL SUTURE OF DUODENAL ULCER—STRICTURE OF THE SMALL INTESTINE FOLLOWING STRANGULATED HERNIA—PATHOLOGY AND TREATMENT OF PNEUMONIA—PARASITE OF CANCER—OPERATIONS FOR GASTRIC CARCINOMA—HAVE NERVOUS DISEASES INCREASED?—THE REAL POSITION OF THE STOMACH.

At the Medical Society of London, February 12th, Ewart exhibited an automatic respiratory jacket for applying continuous pressure to the chest in cases of empyema. It was intended to be worn night and day. A boy who had worn such a jacket for six weeks was also showed. His symptoms had improved and his chest measurements had decreased.

E. H. Willock showed an apparatus for the same purpose, which was not to be worn all the time, but could be used to obtain pressure intermittently. The patient so treated expectorates more freely for a day or so, and then the expectoration is decreased and the symptoms improve.

W. J. Hadley exhibited two little girls, aged eight and nine years, who presented unusual symptoms of rheumatism. The first had had three attacks of ordinary polyarticular rheumatism, and later an attack causing lasting deformity and stiffness of most of the joints, due, according to the skiagrams taken, to soft tissues, the bones showing little variation from the normal. This was, therefore, a typical case of rheumatic arthritis occurring in a child. Antirheumatic remedies had proved useless but the joints improved somewhat under the influence of daily massage and sweating. The other child gave a history of chorea, although not of arthritis. After some days of irregular pyrexia, a presystolic mitral murmur and a systolic aortic murmur made their appearance. Later the occurrence of sudden pain in the left arm, with tenderness and other symptoms, made it almost certain that an embolus had passed into the brachial artery. The radial artery became pulseless.

At the Clinical Society of London, February 9th, H. D. Rolleston spoke of a fatal case of hemopneumothorax of unexplained origin. A man, aged twenty-one years, in apparently good health, was seized with an attack of abdominal pain and diarrhea lasting two days. There was then agonizing pain in the right hypochondrium, radiating to the umbilicus and right shoulder. The next day his right chest was tapped and air and blood came out. In a week he died, and the right pleural cavity was found to contain 60 ounces of blood, but no air. The necropsy was performed in the most careful manner, but no evidence of tubercle, pleurisy, hemophilia, scurvy, hepatic cirrhosis, aneurism, or traumatism could be detected. In fact, the cause of the hemorrhage and air could not be found.

N. Pitt narrated an obscure instance of hemopneumothorax in which, perhaps, an emphysematous bulla had ruptured.

H. Fox told of a man, aged forty-four years, in robust health to all appearances, who was suddenly taken with pyrexia, pains in the chest and signs of pleuritic effusion. He was twice tapped and blood and air withdrawn. The patient was sent away for a voyage, and completely recovered and has remained well ever since. It was noteworthy that three other men employed in the same office broke down with tubercular disease of the lungs.

J. J. Perkins and C. S. Wallace reported a case of successful suture of a duodenal ulcer which had perforated into the abdominal cavity. It is rare that operation under such conditions has been followed by recovery, and, curiously enough, it is still rarer that the diagnosis has been made before the abdominal cavity has been opened. Their patient was a man, aged fifty-two years, who after three days of epigastric discomfort was seized with sudden intense pain without vomiting. The correct diagnosis was made, the abdomen was opened through the right rectus muscle, and the duodenal perforation closed by two sutures in two rows. There was little fluid in the abdominal cavity, but the intestines were turned out and irrigated. A slight gauze drain to the site of perforation was left in the abdomen.

A. Barker protested against the evisceration and irrigation which had been employed. He considered it far safer to wipe out the fluid as well as possible and to leave the rest to the absorptive power of the peritoneum. Even when extravasation is widely diffused, it is possible to clear out both flanks and other parts of the peritoneum by strips of antiseptic gauze.

J. C. Symonds agreed that evisceration adds to the risk of an operation. Not to flush out the abdomen in any case is perhaps going to the opposite extreme. Probably flushing and mopping out with gauze without removing the intestines is the safest procedure.

T. H. Kellock reported a death from stricture of the small intestine following strangulated hernia. At operation the intestine was in such good condition that it was replaced in the abdominal cavity. For three months the patient suffered at times from pain and constipation, and then the symptoms became so severe that the abdomen was opened. The loop of intestine which had been caught in the hernial sac was constricted and adherent to the omentum. The omentum was separated from it, and a lateral anastomosis was made between the afferent and efferent parts of the loop. The patient died, not because of any failure of the anastomosis, but because the loop of intestine went on to gangrene and set up a fatal peritonitis. Apparently, the mesentery of the bowel had been severely affected at the time of the strangulation of the hernia, and after its return to the abdominal cavity the nourishment of the bowel had taken place through the omental adhesions. When these were divided gangrene followed.

At the Liverpool Medical Institution, January 25th, N. Raw read a paper on the pathology and treatment of pneumonia, based on an observation of 1047 cases during a period of twelve years. The general death-rate of the whole series was 23.4 per cent. During the past three years 317 cases of pneumonia were admitted into the Mill-road Infirmary and the death-rate was 34 per cent. Some of the patients were moribund when admitted. There seems to be no reason to doubt that the disease is due to a specific micro-organism, the diplococcus of Fraenkel, influenced by changes in temperature, and a lower power of resistance in the individual. After reviewing the various forms of treatment employed in the past and at present, the speaker gave it as his opinion that no specific form of treatment influences the progress of the disease or in any way cuts it short. He believes that the treatment

of the future will be antitoxic, the serum being obtained from convalescent patients or from immune animals.

W. Carter said that on clinical grounds one must recognize two different forms of pneumonia, (1) simple and tending to recovery, and (2) septic and very dangerous. The intensity of the disease varies in different years, having been greater in 1881 under the influence of the small-pox epidemic, and at the present time under the influence of the epidemic of influenza. He mentioned one condition in which opium is of benefit, namely, after a drop in temperature of 6° or 8°, with the onset of active delirium. The induction of quiet sleep will do much good. At all other times opium is harmful.

February 8th, the discussion was continued. C. J. Macalister, referring to the serum treatment of pneumonia, thought that the argument that the crisis resulted from the production of antitoxin, and that immediate relapse was thereby rendered unlikely, was not maintained in the case of bronchopneumonia, for fresh patches of pneumonia succeed one another, and in croupous pneumonia one attack seems to predispose to another.

J. Hay referred to the influence of the alcoholic habit upon recovery, saying that out of 100 cases which he had watched, two-thirds of the patients who died were alcoholics. He considered valvular cardiac disease to be of less importance in an attack of pneumonia than a degenerate myocardium.

A. E. Davis thought that with careful nursing and treatment, the mortality in pneumonia should not be over 10 per cent. He advocated treatment by carbonate of ammonium and brandy, and thought opium and other narcotics harmful.

In closing the discussion Raw said that he had included all forms of pneumonia in his statistics. The death-rate of genuine lobar pneumonia is probaly about 12 per cent. Carbonate of ammonia is a most useful expectorant and stimulant, and a combination of chloral and digitalis is helpful and soothing. Strychnine is the most valuable heart stimulant. Oxygen is of little value. Many patients require no alcohol, while others need it and are greatly helped by it.

At the meeting of February 15th, K. Montsarrat read a paper on the parasite of cancer, stating that he had isolated organisms from a carcinoma which he had succeeded in growing upon various nutrient media. Inoculations from these cultures made into the peritoneal cavity of guinea-pigs had been followed by carcinoma of the peritoneum and of various internal organs. In these growths parasitic organisms were found in abundance and were again cultivated. While not claiming that the parasitic theory was proved, the reader of the paper said that it afforded a good working hypothesis. He explained the similarity of primary and secondary growths by supposing that the cells of the parent tumor migrated, carrying with them the parasites, and in this manner the structure of the secondary growth was determined. These parasites appear in a variety of forms, according to the circumstances, but morphologically they seem to be identical with the "cancer-bodies" already described.

At the meeting of February 22d, R. Parker spoke of some recent operations upon the stomach for malignant disease. Gastrostomy by Frank's method was four times performed. Two patients died in six months of phthisis, one in a week from bronchitis, and one in three months from syncope. He considered gastrostomy the least satisfactory of temporary operations upon the stomach. Four gastro-enterostomies were performed with success. Two of the patients were holding their own, and two were growing worse from extension of the disease. No appliances were used, but two rows of sutures were inserted, one through the mucous membrane and one through the peritoneum. Excision was twice performed. One patient, whose tumor was shown microscopically to be a carcinoma, was apparently well two years after operation, and the other patient was well a year after operation; but the microscopical examination of the tumor in the latter instance showed it to be a gumma.

F. T. Paul thought that there is danger of the escape of intestinal contents into the stomach after gastro-enterostomy, especially if the opening is made posteriorly. He considered the operation inferior to pyloroplasty as a means of temporary relief.

At the Edinburgh Medico-Chirurgical Society, February 7th, W. W. Ireland took up the question of the increase of diseases of the nervous system which, according to Professor Erb, has been going on for the last thirty years. He considered that the strain of life to-day falls most heavily on the middle classes. But there are many compensations in the way of more secure existence, more frequent amusement, less drunkenness, etc. Ireland had addressed many letters to physicians to learn whether nervous diseases have been on the increase. Most of the physicians replied that they saw no evidence of such increase. A few, from the large towns, thought there had been an increase in the lighter forms of nervous trouble, such as neurasthenia. Monotonous work demanding severe and unremitting attention, such as telegraphy or checking mechanical labor, is most trying to the nerves, and nervous and mental breakdowns are relatively common among persons who pursue such occupations.

At the Royal Academy of Medicine in Ireland, February 2d, Birmingham discussed the form, position, and relations of the stomach as he had found them in bodies hardened by the intravascular injection of formalin. The empty stomach is contracted, not collapsed, and its pyloric portion resembles thick-walled intestine. Its cardiac portion is rounded and attenuated, and its long axis is nearly horizontal. The transverse colon is doubled up over the empty stomach, and lies between it and the diaphragm. In the

first stage of dilatation, the fundus and cardiac portions are expanded, while the pyloric portion remains contracted, and the lesser curve is bent sharply, as in the empty state. In the second stage of dilatation, the pyloric portion opens out, but the distinction between it and the cardiac portion is still well marked. In the third stage of dilatation, this distinction is nearly obliterated. All the axes of the stomach are then enlarged, and the pylorus is carried an inch or two to the left of the median line. There is no rotation around the long axis with raising up of the greater curvature, as is usually described. The distended stomach lies obliquely, its long axis not vertical, as has been taught in recent times, but making an angle of 40° to 45°.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE

Stated Meeting, Held Thursday, March 1, 1900.

The President, William H. Thomson, M.D., in the Chair.

The subject of the evening was the continuation of the discussion of cancer.

Cancer of the Larynx.—Dr. D. Bryson Delavan said that cancer of the larynx is very rare. Its most frequent form is epithelioma. The most important consideration with regard to the affection is its early and certain diagnosis and radical removal. The operation for radical removal of cancer of the larynx is undertaken by but few. The diagnosis of the condition is demanded of many physicians, and even the general practitioner should be familiar with the symptoms which raise a suspicion of beginning laryngeal carcinoma, so that the very important early stage, when radical removal is comparatively easy, may not be passed over. It must be confessed that very little progress has been made in this subject of cancer of the larynx during the last twenty-five years, except as regards surgical procedures. J. Solis Cohen's suggestion regarding the removal of the whole larynx and the attachment of the trachea to the cervical wound is the most important contribution to the treatment of laryngeal carcinoma during recent years. Early recognition of laryngeal carcinoma is one of the most difficult problems in diagnosis. It is extremely important because the neglect of it costs life. At first there is hoarseness. This may last for months, seemingly without cause. In people over forty, continued hoarseness for which no cause can be found should give rise to suspicion. The first sign on the vocal chords is usually an infiltration, small in amount; then a swelling is noted, sometimes diffuse, sometimes papillomatous in character. Finally, there occur two signs that are more or less pathognomonic, these are sudden lancinating pains and loss of motion on the affected side. The pain is very different from that of ordinary sore throat, as patients will usually tell their physician of their own accord, or at least, will do so if questioned about the matter. The loss of motion is due to infiltration of the muscles attached to the arytenoid cartilages. This loss of motion may simulate paralysis or anchylosis of the joints of the arytenoid cartilages. When the infiltration and swelling of the vocal chords is noticed, two things require to be differentiated, tuberculosis and syphilis. Tuberculosis can be excluded by a careful consideration of the history of the patient, by an examination of the lungs, and by the investigation of the sputum for tubercle bacilli. Syphilis may be excluded by the history and, especially, by the therapeutic test of yielding promptly to antisyphilitic treatment. Two to three weeks of treatment suffices to make the decision. Where doubt remains as to the character of the tumor a part of it may be removed and examined under the microscope. As is easy to understand, this may often be misleading. A notable example is that of the late Emperor of Germany. So great a pathologist as Virchow himself examined the portion of tissue that had been removed from the Emperor's throat, yet he failed to find epitheliomatous appearances. The reason for this is obvious. The portion removed may easily be only normal mucous membrane from above the tumor, or it may be laryngeal tissue distorted by the neoplasm but not yet infiltrated with epitheliomatous cells. There are two objections to the removal of a portion of a growth for microscopic examination. The first is that a serious injury of the larynx ensues from the removal of the tissue, and, secondly, irritation tends to accelerate the growth of the neoplasm and this seems to be especially liable to happen in carcinoma of the larynx.

Exploratory Thyrotomy.—Where there is long-continued hoarseness without cause and severe lancinating pain and loss of motion in one or both chords, grave suspicion should be entertained of the presence of malignant neoplasm. If, in addition to these signs, a tumor is found suspicion becomes almost assurance. There is no doubt that in these cases Butlin's advice seems completely justified. When such a tumor is present it should not be allowed to increase too much in size before surgical measures are taken, and an exploratory thyrotomy should be advised. The operation is not dangerous and makes the diagnosis absolute. The improvement in the technic of operations for removal of portions of the larynx of late years has made the results very encouraging. One-fourth of a larynx can be removed without seriously inconveniencing the patient for after life. A patient from whom three-fourths of the larynx was removed three years ago by Dr. Curtis is now able to talk reasonably well and seems only to be suffering from hoarseness. He has been able to resume his occupation and considers himself to be in excellent condition.

In discussion, Dr. B. Farquhar Curtis said that he performed the operation on Dr. Delavan's patient some three years ago. After the removal

of the larynx he packed the cavity for twenty-four hours, then removed the packing and allowed the patient to take food, his head being held over the end of the bed while he swallowed in order that no food might be aspirated into the lungs. The wound healed very nicely, but the formation of the false vocal cords after the operation took a longer time than usual. There was a certain redundancy of mucous tissue which formed folds, thus causing symptoms of stenosis. About a year and a half after the primary operation, a secondary minor operation was done which relieved this stenotic condition, and at the present time the new vocal chords function very well. The patient talks as if he were very hoarse, but is able to carry on his ordinary avocations and to make himself perfectly understood. He is, in fact, in no worse condition that a man with a bad cold.

Cancer of the Stomach.—Dr. B. Farquhar Curtis said that while cancer of the larynx is very rare, cancer of the stomach is very frequent. It represents over twenty per cent. of all the cancers that occur. In men over one-third of the cancers are gastric, in women only 13 per cent. Of late the mortality of operations for gastric cancer has grown constantly less and less. Professor Woelffler of Prague has collected the statistics of 173 cases of gastric cancer operated on by the best German surgeons. The mortality was 31 per cent. This is for operations done during the last ten years. Twenty years ago the mortality was as high as 60 to 80 per cent. Some operators have at present as low a mortality as 25 per cent. Many of the cases were radically cured. Three of them were alive at the end of four years, four at the end of five, one at the end of six years, one at the end of seven years, and three at the end of eight years. This set of statistics constitutes a good proof that in selected cases operation is a radical cure for cancer of the stomach. Early diagnosis is indispensable for successful radical operation. Patients may be divided into those who have a tumor and those without a tumor. Patients with a very large tumor used to be considered inoperable. This is no longer the case. A patient from whom a very large tumor was removed by Dr. Curtis is still alive at the end of two years. If the tumor is freely movable the prognosis is better, but an immovable tumor may be operated on successfully if it is only bound down by inflammatory adhesions which can be readily broken up. Cancer of the stomach is usually in the pyloric region. It must not be forgotten, however, that the mesenteric attachment of the pylorus may become very much stretched and the tumor displaced. It may even be found in the cecal region. When a tumor is found, gall-stones should be carefully excluded, as they may easily produce a hard, nodular feeling that simulates cancer.

Diagnosis without Tumor.—The majority of cases of cancer of the stomach come to the physician at a time when no tumor can be felt, the reason being that the tumor is hidden either behind the liver or beneath the ribs, or is very small and escapes palpation. The suspicious symptoms of cancer then will be vomiting, hematemesis and pain. These symptoms are not, however, at all pathognomonic. Benignant stenosis of the pylorus and ulcer of the stomach may cause them quite as well as cancer. Other symptoms, then, must be looked for to make the suspicion of malignancy sufficient to justify diagnosis. Dilatation of the stomach is not common with malignant disease. Stricture of the pylorus develops but the stomach has usually not been in a sufficiently healthy condition for dilatation to have taken place above a cancerous stricture. The presence of a dilated stomach, then, is presumptive evidence of a benign process. There are exceptions to this rule, but it will usually be found that the cancer in the cases where dilatation has developed arose on the site of an ulcer which had previously caused some stricture of the pylorus.

Chemical Diagnosis.—This is our most valuable auxiliary in cancerous affections of the stomach. The most important element in this method of diagnosis is the presence or absence of hydrochloric acid. The absence of hydrochloric acid strongly confirms the suspicion of the presence of a cancer. In a recent series of over 105 cases in Italy, hydrochloric acid was absent in over 80 per cent. of the cases. Other investigators declare that it is absent in 90 per cent. of cancerous involvements of the stomach. Lactic acid was claimed by Boas to be pathognomonic of cancer. His conclusion in this matter has not been confirmed by the observations of others and, moreover, the presence of lactic acid it not an early symptom and so is not helpful for a diagnosis at the stage when it is most needed.

Digestion of Albumen.—This constitutes one of the most important diagnostic signs of cancer of the stomach. Cancer leads to an atrophy of the gastric glands and this causes a delay in the digestation of albumen or a complete loss af the faculty. Hemmeter says, however, that where only small tumors exist, not enough of the stomach glands are affected to cause any notable diminution in gastric secretion and consequently not in albuminous digestion. There is often great motor insufficiency of the stomach. This occurs even when there is no stenosis of the pylorus, the cancerous tumor being on the anterior or posterior walls. The presence of the tumor seems to interfere with normal peristalsis in these cases. Benign stenosis of the pylorus is accompanied by an increase of hydrochloric acid. Symptoms of stenosis, then, where no hydrochloric acid is present, point in at least 75 per cent. of the cases to the existence of cancer. It is often said that portions of the growth may be obtained for microscopic examination. Theoretically this is a most certain way of making the diagnosis, but it is extremely difficult to secure satisfactory specimens. There is a bacillus described by Oppler and Boas which is said to occur constantly in the stomach when cancer is present. Its discovery is at least confirmatory of other signs.

Practical Rules.—If a tumor of the stomach is discovered operation should be advised if there are any other suspicious circumstances. Either a cancer will be found, or sometimes the thickened base of an ulcer. In either case the condition may be relieved by operation. If symptoms of stenosis are present, a laparotomy should be done in order either to remove the cause by radical operation or a gastro-enterostomy to relieve symptoms. If dilatation of the stomach exists, operate, for the gastroptosis can also be relieved. If the patient has lost a good deal of weight from no obvious cause, if there is a decrease of hydrochloric acid and lactic acid present, an exploratory laparotomy is certainly justified. If blood is frequently vomited an operation should be done. Frequently recurrent pain of an intense character justifies operation. There is danger in operating for pain alone, since this may prove to be due to a neurosis of the stomach. Even a neurosis, however, has been known to be cured by laparotomy and in two cases operated on recently by Dr. Curtis himself, although nothing was found that might be considered causative of the pain except a highly neurotic condition of the stomach, both were relieved by the operation. If there should prove to be no cancer, not only will the operation do no harm but it will almost surely do good. Surgeons have come to the realization that there is a large field for surgical intervention in benignant affections of the stomach. Czerny has reported 77 cases where he operated for benign tumors. It must be remembered that there is considerable danger of ulcer of the stomach leading to the development of cancer. Rosenheim reported 2 cancers out of 50 cases of ulcer of the stomach that had developed during four years of observation. There are now many such cases in literature. Operation for ulcer of the stomach which is giving severe symptoms is really often the best prophylactic for cancer.

Supposed Contraindications.—The mere size of the tumor is never a contraindication. Even extensive adhesions do not contraindicate operative intervention. Where the tumor is adherent to the liver, to the pancreas, or to the transverse colon, portions of these organs may be removed. This increases the danger of the operation, but does not absolutely forbid it. Gastro-enterostomy for the pain of cancer of the stomach is an illusion. The pain is not due alone nor even principally to the pyloric stenosis, but to interference with sensitive nerve-endings in the stomach. This merely palliative treatment has of itself a mortality of nearly thirty per cent. and the results to be gained from it never quite justify the operation. Where the stenosis is very marked and radical operation is out of the question, gastro-enterostomy may be done to relieve the symptoms of obstruction and will give excellent results.

Intestinal Cancer.—Cancers of the duodenum are usually sharply defined in outline and there is no need to cut far away from the edge of the tumor. In the intestine generally the lymphatics run around the gut, not lengthwise. The progress of the growth, then, is in the shape of a ring, but it does not extend much along the intestine. There is consequently a chance for the permanent cure of cancer of the intestine even in old cases where the symptoms have been noted over years. Cancerous stricture of the intestine may give rise to the symptoms of sudden obstruction. The stricture may be of so small a caliber that a cherry-pit or an apple-seed will close it up completely, and yet there may have been no symptoms before the complete obstruction, except recurrent constipation. This constipation in elderly people, with attacks somewhat simulating obstruction which are relieved by purgatives, is always suspicious. The pain of intestinal cancer may be as severe and have all the symptoms of intestinal colic. The most prominent symptom is complete obstruction of the intestine. A subacute form may have developed several times before the severe form of the affection. The attacks are repeated with shorter and shorter intervals. With a history of this kind, very careful examination should be made in order to discover the presence of a tumor. Where the cancer is in the colon, especially if low down, ribbon-like stools may occur; or the small rounded scybalæ, called goat-stools, may be found. At times, of course, there will be mucus or pus in the stools, according to the amount of irritation set up by the cancer. Patients do not, as a rule, die of the cancer, but from acute or chronic obstruction. The symptom of bloody stools may be due to so many conditions that it has very little value for diagnostic purposes.

Cure of Intestinal Cancer.—Under present day auspices in surgery the cure of intestinal cancer is by no means rare. Of 18 cases operated on by Czerny 56 per cent. recovered. Even this mortality is higher than it should be. Operations should be done before intestinal obstruction weakens the patient and before the tumors are large. When tumors are small, even although malignant, the shock of removal is very slight. Colostomy and anastomosis must yet have a prominent place as palliative measures for intestinal cancer. Diagnosis cannot be made early enough to make radical removal always possible. Exclusion of a loop of intestine, or the closing of one end with the opening of the other on the skin, may, in suitable cases, prove of the greatest service to the patient.

Inoperable Cancer.—Dr. William B. Coley said in a paper on this subject that the best treatment for cancer is early and complete removal of the malignant growth. There are cases, however, that become inoperable before the surgeon sees them. To operate rashly on such patients is to invite an almost immediate fatal termination which will deter others suffering from cancer and as yet in an operable condition from submitting to operation. There has been undoubtedly a rapid increase of late years in the number of cases of cancer. Despite surgical procedures three-fourths of them eventually become inoperable.

Some therapeutic measures for inoperable cancer, then, would be most welcome. The administration of thyroid gland, with the removal of the ovaries, in carcinoma of the breast, has been tried in a number of cases. In some of them a good deal of improvement took place, so that it was said we would have to look to the ovaries for the cause of cancer. Further investigation of the subject, however, has not confirmed the preliminary good report. Some good is done, but not much. The injection of alcohol into malignant tumors gives little encouragement.

Inoperable Sarcomata.—The mixed toxins of erysipelas and the bacillus prodigiosus are undoubtedly of service in the treatment of inoperable sarcomata. Round-cell sarcomata are not affected as much by them as are spindle-cell sarcomata. Melanotic sarcomata are affected least of all. In children and delicate persons it is well to filter the toxins so as to administer only the chemical products of the bacilli and not the bacilli themselves. Of course, in no case are the living bacilli injected. The cultures from which the toxins are obtained must be virulent. They should be kept virulent by passage through animals from time to time. The mixed toxins undoubtedly increase the liability to septic infection, so that the hypodermic needle by which they are administered should be very carefully sterilized. Usually it is easy to decide within three or four weeks after the beginning of the injections whether or not it is worth while to go on with them. There are two ways in which the tumors disappear: the first is by sloughing, when the tumors are large, succulent, and mostly composed of cells. Fibrous tumors disappear by resolution and absorption. The toxins may be given for long periods without any harm resulting. They have been given at intervals for two and a half years without causing any serious inconvenience. A spindle-cell sarcoma recurred eight times during four years and each time disappeared under treatment. The patient was a physician and now, six years after the last injection, is perfectly well. So many cases have been treated successfully that now there does not remain the slightest reason for thinking that the tumors were of some other nature than sarcomatous and disappeared in the ordinary course of events. The diagnosis sarcoma has been confirmed by the most typical clinical signs in all cases and in many by microscopic examination of excised sections. Dr. Coley himself has treated 140 cases. Of these 84 were round-cell sarcoma; 3 were completely cured and 40 were improved for some time; 21 were spindle-cell sarcomata, of which 10 disappeared completely, and all were markedly improved by the treatment; 9 melanotic sarcomata were not much affected. Altogether there have been 50 complete successes at the hands of all observers. Risk from the injection of the mixed toxins is practically non-existent. Of 230 cases reported there have been 2 deaths. The treatment is used only for absolute hopeless cases of sarcoma and the statistics of cure are more than 10 per cent. The mixed toxins should be used in small doses after operation for the radical removal of sarcoma, in order to prevent recurrences. Surely if the injections can cause the resolution and absorption or the suppurative disappearance of large sarcomatous tumors, they can prevent the growth of the small portions of sarcomatous tissue which may be left behind after operation and so save the patient from the dangers of recurrence.

THE HARVARD MEDICAL SOCIETY.

Stated Meeting, Held, Saturday, February 24, 1900.

The President, John B. Walker, M.D., in the p. 466.)

Treatment of Whooping-Cough.—Dr. Henry Coggeshall read a paper on this subject. (See p. —.)

Complications.—In the discussion Dr. Daniels said that bromoform seems to give the best results for the treatment of the disease itself. Insufflations of various powders have proved to be of no benefit. The dangers to be feared in whooping-cough come from the complications and treatment should be directed to preventing their occurrence. Good hygiene and plenty of fresh air seemed to be the best remedies for this purpose. The ventilation of the sick-room should be very carefully seen to and the nutrition of the children kept at its acme. It is said by good authorities that whooping-cough is not contagious after it has lasted for six weeks. It is well known, however, that the paroxysms continue after this time. These attacks at the end of the disease are evidently not due to a germ. It is probable, then, that much of the so-called antiseptic treatment of whooping-cough is a mistake, since at a time when there are no germs present the whoops may continue.

Dr. Dillon Brown said that the treatment of whooping-cough is not very satisfactory. The best remedy seems to be belladonna. The amount of this to be given, in the words of an old practitioner, should be "enough." Morphine or codeine should be used to limit the number of paroxysms and their severity. During the intense strain of the paroxysms there is danger of the development of cardiac dilatation. To save the heart as much as possible, then, the patient should be kept in bed during the height of the disease.

Contagiousness of Whooping-Cough.—Whooping-cough is one of the most contagious of children's diseases. The patients should be kept thoroughly isolated. The practice of treating these cases in dispensaries undoubtedly leads to the spread of the disease. As many die from whooping-cough as from scarlet fever or diphtheria. Of course, it is not the whooping-cough itself, but one of its complications, meningitis or

pneumonia, that closes the scene. In very young children the disease is extremely fatal. Dr. Brown has seen three cases in children under a month old, all of whom died. During a paroxysm the children became black in the face and died from asphyxia.

Dr. Brandon said that children suffering from whooping-cough should occupy a large, sunny room, into which plenty of air can be admitted without producing a draft. Another room should be provided into which the patients can be transferred when desired. The children should be kept a half a day in each room, the vacant one being thoroughly ventilated in the meantime. Internally, belladonna, to its physiological effect, with a certain amount of antipyrine and the bromides, to lessen the number of paroxysms, seems the best medicinal treatment. A one-per-cent. spray of resorcin in the nose and throat has been reported to be of service. The inhalation of steam from a steam atomizer is of great value. The vapor of cresoline or of creosote may be added with advantage. A tent can be made by stretching a blanket over an umbrella and beneath this the child, with its mother, may breathe the vapor. The paroxysms are much less under this treatment. It must be borne in mind that the nutrition of the child is of great importance. It should be fed very carefully, then, and if after feeding a paroxysm of cough causes vomiting the child should be fed again.

European Clinical Hints.—Dr. Potter said that Henoch seemed to have confidence in only one drug in whooping-cough and that was morphine. Heubner, his successor as professor of children's diseases at Berlin, recommends atropine. Monti at Vienna advises atropine and morphine. Monti also suggests the use of two rooms. In one of them he burns a certain amount of sulphur and then has the child exposed to the vapor for some hours. He claims excellent results from this method. There are some who consider whooping-cough as a neurosis while others think it an infection. It is very probable that certain neurotic elements always enter into the symptoms and that good can be done by treating any condition from which nervous reflexes may originate. With reference to the etiology of the bronchial pneumonia which so frequently develops during the disease, Monti attributes it to the aspiration of food-particles during the vehement paroxysmal inspirations. This indicates the necessity for keeping the mouth and throat as clean as possible.

In closing the discussion Dr. Coggeshall said that he had used resorcin spray without effect. The fumigation of the sleeping-room by means of sulphur he considers an excellent adjuvant to any treatment that may be instituted. Whooping-cough is not a neurosis nor an infection, but a neurosis *and* an infection, and both conditions should be treated. Cocaine is well tolerated by children and the use of it in four-per-cent. solution as a spray can only be a source of danger when used very negligently.

Alopecia in Hodgkin's Disease.—Dr. Potter reported a case of typical Hodgkin's disease in which the notable feature was complete alopecia. Not only the hair of the head but also the pubic and axillary hair disappeared. The symptom is extremely rare in Hodgkin's disease. There seems to be no mention of it in literature. Death took place from cardiac failure. The heart failure had been preceded by symptoms of enlarged glands pressing on the trachea and nerves of the neck.

Dr. Walker reported a case of Hodgkin's disease in which death had also taken place from the pressure of enlarged glands on important structures in the cervical region.

Dr. Brewer detailed a case in which jaundice, lasting for months and very intense in type, had been preceded by acute pain in the hepatic region. The diagnosis of cholelithiasis was made. An operation was done for its relief, but the gall-bladder was not incised, as no calculi could be felt within it. Some enlarged glands were found in the omentum. One of these was pressing upon the common biliary duct. It was removed, although without any feeling of assurance that it would relieve the symptoms. The jaundice cleared up at once, however, after the operation and has not recurred.

Dr. Lilienthal reported a case of enlarged cervical glands removed by operation. Recurrence took place and some of the enlarged glands were situated within the thorax, so that radical removal seemed impossible. The patient developed a hydrothorax on the right side which, on being tapped, proved to be due to an accumulation of chylous fluid. For two months before death this chylous fluid continued to collect. It was removed every few days. After each withdrawal the chest filled up rapidly. Complete aspiration of the fluid was always followed by relief, but the operation had to be repeated at least twice a week. Finally chylous ascites developed, which also had to be tapped. After this came the fatal termination of the disease.

Dr. Fuller detailed a case of syphilitic liver which had been diagnosticated as cancer. The patient suffered from bloody stools and marked ascites developed. The liver was rough, nodular, hard and very much enlarged. The enlargement melted away, however, under the free use of the iodides. One puzzling symptom in the case for which there seemed no thoroughly satisfactory explanation was the occasional occurrence of gushes of blood from the mouth. These cases are often mistaken for cancer, and Dr. Janeway has pointed out that a hopeless prognosis is often given to patients in whom a course of syphilitic treatment at once begins to have its effect and the case improves very satisfactorily.

Dr. Walker detailed the case of a woman of forty, who for eighteen months had suffered from painful flatulence and loss of appetite and had lost a good deal in weight. She had gone abroad with the idea that a change might do her good. In London she was told that she was suf-

fering from pulmonary tuberculosis. In France the diagnosis had been intestinal catarrh. She lost twenty-six pounds in three months and returned to this country very much discouraged. One surgeon in New York had pronounced her case to be probable cancer of the liver. Another diagnosed some pathological condition of the gall-ducts. Jaundice was not marked and there was no history of attacks of pain such as would occur with gall-stones. An exploratory incision showed the presence of gall-stones in her gall-bladder. Altogether 583 calculi were removed. She began to improve immediately after the operation, has gained in weight ever since and continues to feel in the best of health.

Dr. Brewer said that a great many cases of gall-stones occur in which pain and jaundice and the ordinary symptoms of the presence of biliary calculi are absent. Kehr declares that 80 per cent. of gall-stones fail to produce jaundice. More than half of them never produce any characteristic symptoms.

REVIEWS.

A Practical Treatise on Diseases of the Skin. By James Nevins Hyde, A.M., M.D., and Frank H. Montgomery, M.D. Fifth and revised edition. Illustrated. Lea Brothers & Co., Philadelphia and New York: 1900.

In reviewing a volume of this character, the difficulty at once presents itself of deciding whether it shall be treated from the standpoint of the specialist or of the general practitioner, and the authors must have been confronted with the same problem in writing it. In striving to harmonize the two points of view, they have perhaps laid their work open to a good deal of criticism from either direction and yet, to one who realizes the magnitude of the task, they seem to have achieved their purpose unusually well. In previous editions the book has enjoyed a wide popularity owing to the reputation of the senior author, and, if actual value is to be the measure of success, the present edition will have a still more extensive circulation. The book has been thoroughly revised and carried up to date by the addition of matter upon such recent discoveries as blastomycetic dermatitis and by the rewriting of most of the other chapters, which contain references to medical literature as late as December, 1899.

Speaking generally the volume is very complete: While the space devoted to Etiology and Pathology is not as extensive as we could wish, it is yet ample for the general practitioner; the Symptomology is in most cases remarkably complete, and if the clinical picture of disease is not as sharply drawn as in some other works it is because of the attention paid to atypical cases. But, when all is said, the parts of such a book that are of especial value to the physician at large are the ones devoted to Differential Diagnosis and Therapeutics, both of which have been treated with great care and skill. The one criticism that we have to offer of the latter is that the authors, in their effort to be absolutely fair in the discussion of disputed points, have not given us the benefit of their own individual experiences and preferences. While almost everything that has really proved valuable in Therapeutics is given, yet not enough distinction is made between methods that have been universally serviceable and others which are never referred to except in text-books. An admirable spirit of conservatism is manifest throughout which cannot fail to inspire confidence, and we are pleased to note the amount of credit given to American dermatologists for original work. The illustrations are numerous and helpful, which latter is more than can be said of most works of this knd.

Practical Text-Book of Midwifery. For nurses and Students. By Robert Jardine, M.D., Edin., M.R.C.S., Eng.; F.F.P. and S., Glasgow; Physician to the Glasgow Maternity Hospital. New York: The Macmillan Company. Edinburgh: William F. Clay. 1899.

Based upon the lectures given to the nurses in the Glasgow Maternity Hospital, the work is admirably adapted to the purpose for which it is primarily intended, the teaching of nurses in training schools. The author has succeeded in presenting scientific truth in a manner at once interesting and easily understood by the merest beginner in midwifery. There are many excellent features of the work, not the last of which is the chapter on "Antisepsis and Asepsis." Careful consideration is given to this most valuable part of the nurse's training. We are not in accord with the author in the use of turpentine and carbolic acid, as we believe that other antiseptics, such as lysol and bichloride of mercury, are much to be preferred. The more difficult subjects of "Presentation," "Position," "Labor and Its Management," are presented simply and very clearly. In the chapter on "Care of the Mother and Child," we should advise that, before the use of the catheter, the patient be allowed to sit in a partially upright position, as recommended by Hirst, a procedure which is often attended with satisfactory results. The second week, in our opinion, is still too early, in the vast majority of cases, to allow the patient to be upon her feet, unless circumstances compel her to do so. We regret that the author advises the use of Schultze's method of artificial respiration in the treatment of asphyxia in the new-born. It is rough, dangerous (as he himself admits), dirty, and in no way superior to other easier, safer and at least equally effective methods, such as the Byrd-Dew and Sylvester. The treatment of post-partum hemorrhage is clear and concise, and in the choice of a few excellent measures the nurse will be saved from the confusion often attending upon a perusal of some of our text-books. Taken as a whole, we cannot speak too highly of the practical value of this work, and can cordially commend its use in the instruction especially of nurses in our training schools.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVI. NEW YORK, SATURDAY, APRIL 7, 1900. No. 14.

ORIGINAL ARTICLES.

ON CANCER OF THE BREAST.[1]

BY ROBERT ABBE, M.D.,

OF NEW YORK;

SURGEON TO ST. LUKE'S HOSPITAL.

WE recur again and again to what was, up to recent times, a dreary subject, the surgery of cancer of the breast; and it would still be monotonously dreary were it not for the rays of light which pierce the gloom and lend hope to the operator and victim. The question whether the surgeon can eradicate a cancer of the breast when it is presented to him in a very advanced stage is open to debate, but as to his power over the dire disease when it is taken early there is a growing feeling that the day has come when we are to be emancipated from the stigma of helplessness.

The study of the causations of cancer is not within the scope of my remarks; that has been dealt with by able pathologists. Some light seems to be dawning on the subject, tending to show a bacterial causation which is sustained by clinical resemblances to other disorders of known bacterial origin, but no noteworthy advance in curing the disease has been the outcome of this knowledge compared to the results of a close study of the anatomical relations of the diseased parts. Here, as in the corresponding study of cancers of the tongue, and other organs, the study of the lymphatic system is paramount in importance. For thirty years the rôle played by the lymphatic channels in causing dissemination has been emphasized, but during the last fifteen years, since the researches of Billroth, Haidenhain and others, and later of Halsted and Stiles, the minute anatomy of the efferent lymphatics from the cancer have given exact demonstration that recurrence is *always* along these lines, and that carefully detailed dissection of them at the time of operation on the breast points the way to the only method of eradication.

Incidentally, additional endorsement is positively furnished to the belief that cancer is, in its early life, a purely localized disease. Thus we have the corroboration of the fact seen in every surgeon's experience, that cancer, as shown in the lip and skin, where there is less active lymphatic circulation, can be eradicated, and immunity is seen to follow for a lifetime.

But there are some regions of the body, the tongue, breast, uterus, etc., where the absorbent channels are so free that the spread of the infection is rapid and deep, hence, more early and active surgical work is needed to accomplish the same end.

Progress toward the cure of mammary cancer has come from the recognition of the following anatomical distribution of the lymphatics:

1. Those which drain the mammary gland directly toward the axilla, through parallel channels in the cellular tissue, coursing from the axillary edge of the gland to the axillary vein, interrupted by occasional lymphatic glands, finally concentrating in several channels lying upon the axillary and subclavian veins, mostly upon its anterior surface and entering the neck at the junction with the jugular.

2. A series extending from the mammary gland directly outward to the overlying skin communicates with the lymphatics of the skin itself.

3. A series from the deep aspect of the gland passes directly to the bed of cellular tissue between the gland and the pectoral muscle, where it is joined by lymphatics emerging from the pectoral muscle, and these together travel toward the axilla upon the pectoral fascia.

4. Another series extends toward the sternum and is associated with the veins, penetrating the sternal part of the pectoral muscle and thus enters the mediastinum.

Clinically, it is observed that the segment of the mammary gland, which is the seat of the disease, determinies which series of lymphatic channels will be most involved. The axillary section receives by far the greater part of the infection. When the superficial part of the breast is first involved, the skin becomes infected and the disease spreads in its lymphatics.

In the pectoral aspect of the gland, the lymphatics upon and beneath the muscle are quickly and profoundly infected, and it is observed that the disease will penetrate against the normal lymphatic current and, in many cases, enter the pectoral muscle, although it was at one time believed that by removing the pectoral fascia the outposts of the disease in this direction were thoroughly removed. In later stages of absorption, the more distant lymphatics of the neck and of the pleura are demonstrated to have been infected.

The entire situation, therefore, presents an orderly progress strictly along anatomical lines, and it is the knowledge of this fact, as we shall see, that has given the great impetus to surgical zeal in attempted extirpation. The phase of the spread of the disease by absorption must be supplemented by a recognition of the facts of infiltration of contiguous parts by actual proliferation as when the sternum and ribs become infected

[1] Read before the New York Academy of Medicine, February 15, 1900.

by contiguity. The most essential fact for the surgeon to remember, however, is the "lymphatic system of absorbents."

The breast is the seat of several varieties of tumors, which for present consideration we shall discount adenomata, andenofibromata, cysts, and sarcomata. We shall leave them entirely out of consideration as they do not partake of the clinical history of the infectious cancer, although they are essentially a proliferation of the mammary tissues. They are not clinically classed as malignant. The adenomata are strikingly like carcinomata in feeling, and, doubtless, are frequently made the basis of "cure" by the charlatan.

Corroborative of the anatomical channels of infection we see the clinical evidence when we recall the old-time methods of operating. Let us go back a few years to the time when operations for cancer of the breast meant removal of the mammary gland only; then, the recurrences were uniformily in the axilla, neck, and in the skin. To-day, the axilla is regarded as primarily contaminated, almost as soon as any tumor can be recognized in the breast. Examination of 100 consecutive cases has demonstrated that the axillary glands are practically *always* involved, hence, good surgery demands the entire dissection of the axillary lymphatics. The surgeon realizes, however, that he has compelled absorption to travel by the superficial anastomosis; and thus we find that recurrences are now more often than formerly seen upon the skin; this carries with it an additional demonstration that the superficial lymphatics must have harbored infecting material beyond that which was apparent to the naked eye; and that there has been an outcropping of the uneradicated remnants of the original infection, which might have been prevented by more extensive removal of the skin at first.

These invisible remnants of the disease are to some extent demonstrable by a method resorted to at the time of operation by Stiles and others, consisting in the immersion of the extirpated parts in 5-per-cent. nitric acid, for a few moments, followed by immersion in alcohol, by which minute outlying infected points can be demonstrated on the cut edges if the surgeon has failed to cut wide enough of the disease. This method gives added security to the operation. Most operators, however, prefer to estimate by experience when they have given a wide enough birth to the disease. The tendency on the part of all recent operators is to make more extensive removal of the skin than was formerly thought necessary, regardless of securing apposition of skin-edges in cases where the disease has invaded the surface of the gland. The cardinal rule of operation is to fill the large skin defect by Thiersch grafts or allow healing by granulation. It is not necessary here to give in detail the methods of operating now so well known to every surgeon and commonly described in recent text-books, based largely on Halsted's admirable description, in 1894. This has been supplemented by still more extensive extirpation of the supraclavicular lymphatics in all bad cases. The profession now recognizes that in the most celebrated and prolonged operations as now performed, requiring not uncommonly two hours or more, the extreme care in controlling every bleeding point, making the operation comparatively bloodless, has largely removed the element of shock, and thus death from operation is of the rarest occurrence. Several series of 100 consecutive operations have been recorded without fatality.

Too much emphasis cannot be laid upon the operative infection of the wound by cutting infected glands and lymphatic channels, or discharging into the healthy wound infected cells squeezed from the parts being removed. This danger is recognized by the best operators and is analogous to the recognized risks of autoinfection of the patient in removal of tubercular disease, as in caseating lymphatics or in resection of tuberculous joints. It has often seemed to me that the preparation of the patient prior to operation on mammary cancer by severe and sometimes harsh scrubbing of the skin of the operative area by the nurse has a measure of risk in disseminating the disease in the cutaneous lymphatics, which may in a measure account for some recurrences in the neighborhood of the scar, which is one of the most frequent sites for the miliary deposits. For this reason I advise the least friction and handling consistent with cleansing the skin before operation. Infection of the areola tissue by escaping cells is no myth and has been often demonstrated by such traumatisms as exploratory needle-punctures into malignant growths or along the track of the needle in aspiration for cancerous effusion in the pleura.

To determine the actual value of the great amount of work done in this important field during recent years, one must, in a word, be able to state the length of time after operation that the patients have been rid of disease, and what approach has been made toward eradication. This end may be arrived at in two ways; first, by the statistical method, and, second, by what I may venture to call the "personal impression" of surgeons. Either method is open to deception, and yet with care may be made to yield the truth. Large groups of cases gathered from many sources, extending over perhaps twenty years, would include much that does not represent the latest thorough methods, while smaller groups of individual operators either may not give long enough periods to show values in the time of immunity, or else may represent picked cases in the hands of some operators who refuse cases that are extensively malignant. Prior to recent improved statistics the best consecutive reports by well-known surgeons gave practically no radical cures, and the speedy local recurrences were ranged from 60 to 85 per cent. Immediately upon the adoption of more radical methods the change in statistics recorded by the same great authorities showed a radical cure could be accomplished in from 11 to 30 per cent. (Volkmann, Billroth, König, Küstler, Bergmann and others.)

By "*radical cure*" was meant, as expressed by Volkmann, immunity for three years after operation. The most earnest and extensive work has been conducted throughout Germany, but none more thorough than that accomplished in our own country at Johns Hopkins University. Without ignoring the able contributions of Weir, Bull, Dennis and others, one may speak of Halsted's statistics as representing the best as yet attainable. In the *Annals of Surgery*, vol. xxviii., for 1898, Halsted records the results of 133 operations done at Johns Hopkins during the nine preceding years; 41 per cent. are living without recurrences and without any signs of metastases; 76 of the 133 survived more than three years, 10 of them died more than three years after the operation, one died as long as five and a half years. Of these 10, one had local recurrence. Forty patients, or 52 per cent., lived more than three years without any regionary sign of recurrence. In 67 cases, the supraclavicular fossa was dissected clean of the lymphatics, of which 34 per cent. revealed cancer-cells in these tissues. Four cases among those whose necks were involved are living and free from metastasis after more than three years subsequent to operation, two of which were alive over four years after the primary operation. Where the supraclavicular fossa was surgically cleared of glands primarily, which was done 53 times, the tissues were found involved in 23 per cent.

In an article published in the *British Medical Journal*, June 17, 1899, by Stiles of Edinburgh, on "Cancer of the Breast," he mentions the statistics of Mr. Cheyne and says that 51 per cent. of all cases operated on by him since 1890 are alive and well at periods varying from three years and nine months to nine years. Stiles emphasizes the result of extensive microscopical examination, proving the course of lymphatic absorption in the spread of the disease to have been mainly by the lymph channels accompanying the venous blood-vessels; he regards the retromammary tissue as infected at an earlier date than the skin lymphatics. He says that in 30 per cent. the cancerous nodules have been found on the posterior surface of the pectoralis major, and adjacent to the course of the thoracic vessels in about 30 per cent. In this number of cases the muscle itself was usually found free from the tissue, so that one may say retropectoral lymphatic invasion occurs in at least one-third of all mammary cancers.

My own personal experience in pure carcinoma of the breast, confined to my notes of the past fifteen years only and excluding all cases of mammary cysts, sarcomata, adenomata, or adenofibromata, of which there were many, shows 33 cases in private and 90 in hospital practice, a total of 123 cases. Not one death from operation has occurred in my long experience. I have not been able up to this time to search far into the present status of most of these. I shall note, therefore, that of the 33 private patients which ought to represent the average of the others, I have very recently heard of 18; one survived six years; one five and a half years; four, four years; three, three years; five, two and a half years, and four, one and a half years. Thus about 25 per cent. have reached the three-year limit and nearly as many more have approached it.

Let us disconnect our mind for the moment from the statistical review of the subject and regard the personal estimate of modern operative work of all experienced surgeons, and we will find to-day that it is the expression of men, who have passed through the stage of pessimism which was quite universal up to fifteen years ago, that they are now renewing their efforts at eradication with high optimism. It does not take more than a few cases passing the three-year limit to inspire an operator with the great value of advanced work, proving to his experienced eye that the disease has started as a local affair and was at an early stage absolutely under control, and in the latter stages subject to limitations. Such results as three years' immunity are now within the easy reach of all good operators.

Granted that the removal of the apparent disease and its complete eradication are two different matters, the *latter* of which is not always possible, it still remains proven that the surgical dissection of the extensive lymphatic involvement gives these advantages over non-operation: (1) The pressure of the cancerous masses in the axilla and neck, producing inevitable edema of the arm and extreme neuralgia, is not seen. (2) The cachexia, formerly so distressing a feature of persistent absorption, is now rarely seen even when recurrence ensues. This is equally true in operations for cancer of the stomach, bowels or rectum; the products of cancer-growth cease to poison the system and the patient usually acquires and maintains a good color.

Finally, recent experience shows that a recurrence of cancer after operation need not discourage the patient or surgeon. If it be speedily and thoroughly attended to, there is still a strong probability of its eradication, as the recurrence is not a return of the disease, but a continued growth of invisible metastatic foci left at the time of operation.

13 West Fiftieth Street.

MALIGNANCY.

By ARTHUR L. FULLER, M.D.,
OF HOUSTON, TEXAS.

While there are many diseases which might aptly be termed malignant, inasmuch as their tendency is invariably to produce death, no means being known by which such a termination can be averted, the term "malignant disease" has been restricted to certain tumors, which are characterized clinically by a group of more or less constant and well-defined features, *viz.*, rapidity of growth, a tendency to recurrence after removal, glandular infection and general dissemination, and a condition of progressive ill-health ending in death, which seems to be due

to some special form of pathological activity not at present well understood. While this group of features presents a striking clinical picture of malignancy, it by no means follows that they are all essential features, for the term implies some special form of pathological activity, and many of them are due to manifestations of cell energy which exist, even if not to the same extent, in the benign tumors. Such features cannot be considered anything more than the accompaniments of the condition which really constitutes malignancy.

The methods by which cell energy manifests itself are reproduction, nutrition and function, and since the cells of these tumors cannot possibly have any function beyond that of self-nutrition, it is evident that, in considering them, we have only to deal with their reproductive and nutritive activity, and it is far from difficult to show that each one of the above-mentioned clinical features bears a direct relation to one or the other of these forms of cell energy, even if it be not actually dependent on them.

Rapidity of growth, glandular infection and general dissemination are dependent solely upon the reproductive activity of the tumor cells, influenced to some extent by their anatomical arrangement, which seems to be the determining factor whether internal dissemination or glandular infection shall take place. Thus we find that in certain of these tumors, whose cell growth takes place along the lymph spaces, we have lymphatic infection; others whose cell elements come more closely into connection with the blood-vascular system are characterized by general dissemination, the pathological process being in each case the same, *viz.*, reproductive activity of certain cells or groups of cells which have been carried off by one or the other current. Pathologically, the primary and secondary growths must be considered as one tumor and their activity must be viewed from this standpoint, since, if we leave out of the question any interference with the function of important organs, such as might equally well be caused by the presence in them of a benign formation, it can only be influenced by the amount of their active elements, and can, therefore, be no greater than if they were all gathered together at the site of the original tumor instead of being scattered. The influence of the secondary growths on the patient's health, then, is dependent mainly on the fact that they constitute an addition to the active elements of the original tumor, although it may be increased by their interference with the functions of important organs. Since they are merely manifestations of the reproductive activity of the tumor cells, and since that same reproductive activity exists, even if not to the same extent, in the benign tumors, they cannot be considered essential features of malignancy, but must be looked upon rather as clinical accompaniments.

Cachexia Ending in Death.—In addition to the effects on the system of interference with the functions of important organs, exhaustion from pain, discharge, sepsis due to ulceration, etc., there is a state of progressive ill health, ending in death, peculiar to these tumors, which implies some special form of pathological activity not met with in other diseases. Since this state of health is not an accompaniment of benign formations, and since the other clinical features of these tumors are but different manifestations of a reproductive activity which is present in benign formations, it alone can be looked upon as the essential feature of malignancy, the special form of pathological activity to which it is due constituting malignancy. Therefore I shall define malignancy as "an inherent tendency to the impairment of health and destruction of life by some special pathological activity apart from any interference with the function of important organs," and it is to such tendency I shall in this paper restrict the use of the term.

To What is Malignancy Due?—In considering this question we have two points on which to base an opinion: First, the relation it bears to the structure of the tumor, and, second, the peculiar nature of the progressive ill health which is its essential feature.

With reference to its relation to the structure of the tumor, a slight consideration of the different varieties of the so-called malignant tumors shows that it varies in degree with the *type* of cell of which the tumor is composed and with the *character* of those cells. In the epitheliomata (squamous and columnar), tumors whose cells are of different types, as regards the possession of nutritive or chemical activity, but whose cells closely resemble normal, fully-developed cells of the type to which they belong, both in character and in their arrangement in the alveoli, malignancy, in the sense to which I have restricted the use of the term, does not exist; for such tumors tend to impair health and destroy life solely by better understood methods and not by any special pathological activity peculiar to them. That this is the case few will be disposed to dispute, for all clinical evidence tends to support such an assertion, the loss of health accompanying them being in direct relation to the amount of ulceration with its accompanying pain, discharge, hemorrhage and septic absorption, or to the involvement of important organs and consequent interference with the nutritive processes which are necessary to the well-being of the organism. In the carcinomata, on the other hand, a class which includes encephaloid and scirrhus with all varieties intermediate between them, the cells of which are of the type of glandular epithelium, although varying in different degrees from normal fully-developed cells of that type both in character and in their arrangement in the alveoli, the tendency to impair health and destroy life is a prominent feature, its prominence being greater than in tumors whose cells belong to a type which has less nutritive or chemical activity, and being also in direct proportion to the difference of the tumor cells from normal fully-developed cells of their type. It is most marked in encephaloid, the

cells of which sometimes so closely resemble elementary embryonic cells, as to be indistinguishable from those of small round-celled sarcoma, and becomes less marked through the intermediate varieties to scirrhus, the cells of which more nearly resemble normal fully-developed epithelium in their character. In the sarcomata, the cells of which are of the connective tissue type, a type which possesses less nutritive or chemical activity than glandular epithelium, this tendency also exists, although to a less extent in all except the round-celled sarcomata. It varies in degree with the difference between the tumor cells and normal fully-developed connective tissue, being greatest in the small round-celled sarcomata, the cells of which are purely embryonic in character, and diminishing as the cells approach in character more nearly to fully-developed connective tissue. The malignancy of these tumors, therefore, may be said to exist in direct proportion to the nutritive or chemical activity of the *type* of cell of which they are composed, and in each type in proportion to the variation in *character* of the tumor cells from normal fully-developed cells of their type, being most marked, as regards class, in tumors whose cells belong to the type manifesting the greatest nutritive or chemical activity, and in each class most marked in those tumors whose cells differ most from fully-developed cells of their type. It is hardly conceivable that such a close relation should exist, unless it be a case of cause and effect, malignancy being the expression of some abnormal cell-metabolism, a supposition which also has in its favor the peculiar nature of the ill health produced by malignant tumors.

The cachexia of malignant tumors bears a more than superficial resemblance to certain other conditions, the cause of which is well known, although perhaps not so well understood. These conditions are myxedema and Addison's disease, each of which depends on the absence or destruction of certain glands, whose functions, although imperfectly understood, are evidently intimately connected with the health of the organism. Whether those glands act by extracting certain toxic substances from the blood, returning them in a different and innocuous form, or by producing some secretion which exerts a restraining influence on cell-metabolism, preventing the formation of such substances or neutralizing their effects, the fact remains that disease or destruction of those glands means death by some condition resembling a toxemia, caused by the retention in the system of some of the products of cell-metabolism, which their function is to remove or neutralize. In the cachexia of malignant disease there exists a precisely similar condition, masses of more or less undeveloped cells, of different types, pouring into the system the excrementitious products of their metabolism, products which may be normal as regards the embryonic cells themselves, and yet injurious to the general system in the absence of an organ bearing a relation to them similar to that borne by the thyroid and adrenals to the products of the metabolism of fully-developed tissues. In the thymus such an organ exists.

Since the thymus exists only during fetal and infantile life, its functions must be connected with certain processes of early life which are absent later, their absence obviating the necessity of its continued existence. Since early life is the period in which the reproductive activity of the cells is most marked, it is probable that there are at that period many cells existing which have not yet attained the full development of their type and are, therefore, still embryonic in character, and that it is with the products of the metabolism of these cells that the functions of the thymus are connected. Such is the only theory which rationally accounts for the short existence of the thymus, for if its functions were connected in any way with the metabolic processes of fully-developed tissue, they would also be a necessity of later life, and its existence would, therefore, be prolonged. The activity of the thymus is, therefore, probably exerted in one of the following directions: The extraction from the blood of some products of embryonic cell-metabolism, which are injurious to the system, and their return thereto in a different and innocuous form; the secretion of some substance which neutralizes the injurious properties of such products, or regulates the metabolism of embryonic cells preventing their formation; or possibly, although not probably, the secretion of some substance which stimulates the upward progress of embryonic cells toward the full development of the type to which they belong, its relation to embryonic cells being analogous to the relation of the thyroid or adrenals to fully-developed tissue. The fact that the structure of the thymus indicates blood-formation as its chief function renders this view none the less tenable, for, even if such be its chief function, it may also possess the subsidiary function of internal secretion, such as we are beginning to recognize in certain other organs, notably the testicle and ovary.

This likeness between the cachexia of malignant disease and the cachexiæ of myxedema and Addison's disease, combined with its relation to the cell structure of the tumor, renders it more than possible that the cachexia is due to the retention in the system of products of embryonic cell-metabolism, and that the formation and excretion into the system of such products is the special form of pathological activity, which constitutes malignancy.

It is, therefore, not impossible that the administration of some preparation of the thymus, preferably an extract by intravenous injection, may be of use in the treatment of those malignant tumors whose cells are embryonic in character, *viz.*, the carcinomata and sarcomata. Since their malignancy seems to be intimately connected with, if not absolutely dependent on, the embryonic character of their cells, its exhibition might be of service in hindering the progress or lessening the degree of the ill health attendant on them, and so prolong life in such cases as are beyond operative

interference, and possibly, by improving the general health, bring some cases within reach of the knife which must otherwise be left unrelieved.

To sum up: Malignancy is a term which implies some special form of pathological activity, not present in other conditions.

Since the cachexia alone seems to depend on forms of cell energy which are absent in other conditions, it alone must be considered the essential feature of malignancy.

The relation of cachexia to the embryonic character of the tumor cells is such as to suggest that it is due to the retention of products of embryonic cell-metabolism in the system, constituting a form of toxemia; therefore, the special form of activity, which constitutes malignancy, is probably the formation and excretion into the system of such products.

This suggestion is borne out by the fact that the presence of embryonic cells pouring their metabolic products into the system, in the absence of the thymus gland, constitutes a pathological condition similar to those present in myxedema and Addison's disease, diseases in which the loss of health closely resembles the cachexia of malignant disease.

Therefore, the administration of thymus in malignant disease might prove of service in sustaining the patient's strength, just as the administration of thyroid has done in myxedema and suprarenals in some cases of Addison's disease.

CAUSES, DIAGNOSIS, AND TREATMENT OF CYSTITIS.

By RAMON GUITERAS, M.D.,
of New York.

In preparing this paper my object has been to present the subject, not as I would if treating of it before a body of specialists, but rather in the light in which the general practitioner views it. He looks upon cystitis in a general way and does not interest himself in the finer points which appeal to the specialist, being merely desirous of knowing whether he is dealing with the disease in question, and, if so, its cause and the best means of permanently relieving the patient of his suffering.

The pathology of the disease in its various forms is most interesting, but I have purposely avoided bringing it into the paper, except so far as is necessary in considering the pathological elements found in the urine or discharges, which point to the cause and localization of the trouble, and furnish a valuable aid in differential diagnosis.

We are taught that the three cardinal symptoms of cystitis are, frequency of urination, pain, and pus in the urine; but such symptoms may be associated singly or combined with other diseased conditions, and although we feel reasonably sure that we are dealing with cystitis, when these three symptoms are present, still there are instances in which this rule of three does not always apply. This is manifested in certain cases of cystitis associated with paralysis or with cord degeneration, in which both pain and frequency of urination are absent.

On the other hand an irritable bladder gives rise to the same subjective symptoms as cystitis, but as pus is absent from the urine we do not mistake the condition for cystitis, but look for some cause of the trouble other than an inflammation of the mucous membrane of the bladder. We find it due, perhaps, to a congestion of the vesical neck, or to a disease of the neighboring tissues, as the uterus or rectum, or to some foreign body in the bladder, to some pathological condition of the bladder-wall, to irritating constituents of the urine, or, finally, to some disease of the nervous system. Nor must it be thought that frequency of urination, pain, and pyuria are the only symptoms of cystitis, since hematuria frequently occurs, as well as retention and incontinence.

Almost all diseases of the genito-urinary tract, from the posterior urethra to the kidney, cause frequency of urination, and often pain, referred to the small of the back, the loins, the perineum, the thighs or the testes, so that even although in addition to these two symptoms there is pus in the urine, it is essential before making a diagnosis of cystitis to ascertain that the pus comes from the bladder and not from the urethra or the kidney. The history of the disease as given by the patient will usually be of great service in determining this. If, however, there is a doubt, it is well to examine the urethra, anterior and posterior, for inflammation and purulent discharge, and then turn our attention to the urine in the bladder to see whether the pus comes from an inflammation of the bladder-wall or from the kidneys or ureters.

Blood is frequently found in the urine but generally not in large amounts, excepting in tumor cases. In cases of cystitis it is usually due to rupture of the vesical capillaries. When there is an acute inflammation about the vesical neck some blood may be expressed after urination, although it may be mixed with the urine. In cases of stone the mechanical irritation is sufficient to cause blood in the urine, while in tuberculosis it may be due to ulceration of a blood-vessel in the bladder-wall. One frequently sees, on examining a case of chronic cystitis by the cystoscope a turgid vessel in the bladder, a true varicosity, which looks as if it would break at the slightest touch, with increasing bladder tension, or with a sudden expulsive effort.

For the sake of clearness I shall discuss cystitis in the acute and chronic forms, merely touching upon the many subvarieties of each during the consideration of causation and treatment.

Acute Cystitis.

Cause.—This is always bacterial and is generally due to extension of an acute gonorrhea from the urethra during the third or fourth week,

or to posterior urethral instrumentation during an attack of posterior urethritis. Many of the cases, spoken of as inflammation of the bladder complicating urethritis, are not cases of acute cystitis but of acute posterior urethritis. Injury to the blood and nerve supply of the bladder during confinement, or pelvic operations, whereby the resistance of the tissues to the invasion of bacteria is diminished is almost invariably followed by acute cystitis. There are certain conditions which predispose to acute cystitis in an individual suffering from gonorrhea. These are congestion or distention of the bladder from whatever cause, undue exercise, as bicycle or horseback-riding, and exposure to wet or cold.

Symptoms.—In the beginning of an attack there is often depression, nausea and loss of appetite, although there is no febrile movement. Urination is frequent and precipitate, occurring sometimes as often as a hundred times in twenty-four hours. Pain in the perineum radiating through the urethra and along the thighs, and tenesmus in the neck of the bladder are almost constant, a brief interval of relief following complete emptying of the bladder.

The urine is acid and of normal specific gravity. It is turbid from the amount of pus present, and is pale or highly colored, according to the amount of fluid ingested. If the urine is concentrated there may be blood enough in it to give it the color of thin prune-juice. The microscope reveals bladder epithelium, pus, blood, bacteria and perhaps crystals. Recto-abdominal palpation gives pain in the trigone, and the bladder is extremely sensitive to the introduction of fluid or instruments.

Diagnosis.—Acute cystitis may be confounded with posterior urethritis, prostatitis, seminal vesiculitis and vesical irritability.

Posterior urethritis is the most common antecedent of acute cystitis. The line between this condition and acute cystitis is not a finely-drawn one, as the neck of the bladder is simply a continuation of the posterior urethra, and it is easy for the inflammation to extend along the posterior urethral lining into the bladder. In fact, that part of the urethra above the veru montanum closely resembles bladder in its construction, while that below is more like the remainder of the urethra. As has already been said, many cases of acute gonorrheal cystitis are not cystitis at all, but simply attacks of acute posterior urethritis. It must be remembered that in this condition the pus flows backward into the bladder, so that a great amount of it is contained in the urine, just as is in acute urethritis. Various methods of diagnosis between the two have been proposed by different authors, but in my opinion the most important are the three-glass test and the use of the microscope. If the urine is passed into three glasses, the third glass will contain as much pus as the other two if the case is one of cystitis, while in a posterior urethritis the first glass will contain a greater amount of pus than the other two, with urethral shreds in addition. The microscope will reveal the location of the disease from the variety of epithelium in the urine.

Acute prostatitis is also confounded with acute cystitis, but here, as a rule, the febrile element is marked. Guyon says that in an acute cystitis there is never fever, and if this occurs it is due to some other complication. In acute prostatitis there is often urinary hesitancy, or even retention, the reverse of which, precipitate urination and even false incontinence, occurs in cystitis. There is often pain in the rectum during defecation, or when sitting down, in prostatitis, which does not occur in cystitis. Rectal examination in prostatitis would reveal general enlargement of the prostate gland, or localized inflammatory thickening of one lobe, or a part of one with tenderness on pressure.

Acute seminal vesculitis may be mistaken for acute cystitis, for in this condition there is often frequency of urination, a sense of fulness over the pubes, heaviness in the perineum, a feeling of pain and a burning in the neck of the bladder, with tenesmus. There is, however, very little pus in the urine. The first specimen contains some pus and shreds from the posterior urethritis usually associated with it, whereas the second specimen is clear. The microscope shows no evidence of cystitis. Rectal examination shows the vesicles to be enlarged and tender, and after the inflammation has begun to subside quantities of detritus can be expressed into the urine by massage.

Vesical irritability is usually due to a congestion about the neck of the bladder or posterior urethra, depending upon hyperacidity of the urine, or the presence in it of irritable oxalate of lime crystals, or an irritable condition of the prostate or vesicles. Exposure to cold also causes it at times. In these cases there is no pus found in the urine, as there is in cystitis. It is probable, however, that most cases of so-called irritable bladder are found in patients who, having a chronic inflammation of the posterior urethra, or of the adnexa, bring on a slight exacerbation through excessive coitus, overeating or drinking, or exposure to wet or cold.

If, in any case, differential diagnosis cannot be made by other means, the cystoscope may be resorted to, although as a rule this instrument should never be used in cases of acute cystitis, as it wounds the mucous membrane of the bladder and tends to aggravate the inflammation. In cases in which it has been employed for purposes of investigation, the appearance of the sides of the bladder-wall in acute cystitis, as seen through the instrument, is that of an edematous and very much congested mucous membrane, the vessels of which are dilated. The epithelium is seen to have been cast off in places, and long, thready streamers of it float from the bladder-wall. Hemorrhagic spots or streaks are sometimes noticed.

Chronic Cystitis.

The causes of chronic cystitis are active and

predisposing. The active cause is the entrance of pathogenic germs into the bladder when the predisposing causes are present. Among the predisposing causes first of all we have congestion. This may be due to the condition of the urine, such as the presence of superabundant crystals of uric acid, or oxalate of lime; to certain drugs, such as cantharides; to overindulgence in alcoholics or sexual excitement, when a posterior urethritis is present; to the presence of some irritating medium in the cavity or wall of the bladder, such as calculus, tumor or tubercle. It may also be due to obstruction, as stricture and enlarged prostate. These cause congestion by the effort of the bladder to overcome the obstruction, also by distention of the bladder with residual urine. In stricture there is usually a little dilatation behind it, which allows a small amount of residual urine to remain after micturition. This may decompose and keep up urethral irritation and favor the local growth of microbes in a place where they may be easily pushed into the bladder by instrumentation in making a diagnosis, or withdrawing urine in retention.

In prostatic hypertrophy there is an obstruction to the return of blood from the vesical veins through the compressed prostatic veins and thus there is a passive congestion, most marked when the patient is quiet at night, for in the daytime the muscular effort of moving about favors the circulation.

Symptoms.—In chronic cystitis the patient has usually been ailing for some time. The symptoms vary much in their development, duration and intensity. Frequency and pain are not, as a rule, so marked as in acute cystitis, excepting during exacerbation. The patient urinates, perhaps, ten to twelve times during the twenty-four hours. Pus in the urine is the only symptom which is never absent, but as this may occur in many other conditions we must be on our guard against a hasty diagnosis.

The urine is generally light in color and alkaline, of a lowered specific gravity, containing a slight amount of albumin, perhaps some blood, with pus in abundance. On examining it in three glasses as it is evacuated from the bladder, the first and third usually contain the greatest amount of pus. When the urine is allowed to settle, it forms a more or less dense deposit on the bottom of the glass, above which there is a cloud of muco-pus. When it is ammoniacal, the odor is characteristic and there is a glairy mucilaginous substance present which adheres to the vessel in which it is contained. In this, as in the acute condition, the microscope is a most valuable aid to diagnosis. Bladder epithelium of the first and second layers is found in abundance, together with crystals and perhaps blood, especially in the ulcerative forms, while the discovery of the particular germ, or germs, actively concerned in the inflammatory process is of great assistance, not only in diagnosis, but in prognosis and treatment.

Differential Diagnosis.—In making a diagnosis of chronic cystitis certain other conditions outside of the bladder have to be considered, as chronic posterior urethritis, chronic prostatitis, kidney lesions, bladder irritability, and various affections.

In a chronic posterior urethritis there is increased frequency of urination. There is often some pain and tenesmus after overindulgence in coitus, drink, or exposure to cold. Pus, however, is found only in the shreds washed out in the first urination, in the three-glass test, and the microscope fails to reveal the products of bladder inflammation.

In chronic prostatitis a posterior urethritis usually exists, and perhaps prostatorrhea. The symptoms are about the same as in chronic posterior urethral inflammation, but here also under the microscope the urine would fail to show the products of cystitis.

The diagnosis of cystitis from surgical kidney is usually not difficult, although disease of these two organs may often be associated, one dependent upon the other, as, for instance, a tubercular cystitis may be secondary tuberculosis of the kidney, or a pyelitis, or a pyelonephritis may follow a cystitis due to obstruction. In kidney lesions we usually have pain in the loins, and on palpation, perhaps tenderness, or a marked enlargement of the kidney. Disease of either organ may give rise to frequency of urination, but in bladder cases the frequency is usually more marked, and the pain associated with it is more often behind the pubes, or in the vesical neck. The pain in the kidney cases may extend down to the bladder, but it is usually most persistent in the lumbar region. Clinically the pyuria varies somewhat in these cases. In cystitis the pus is usually found in alkaline urine, while in pyelitis the urine is acid. In cystitis the pus is a constant constituent of the urine: in kidney disease it may be intermittent. In cystitis it is usually in larger quantities than in pyelitis.

The microscope shows the pus-cells coming from the kidney to be more degenerated. It also shows more epithelium present in the urine of cystitis. In the pus of pyelitis it shows, sometimes, large cylindrical plugs coming from the papillary ducts. In addition to this in kidney cases we may see hyaline, granular, blood and epithelial casts with pus and even particles of renal tissue. Although it has been contended by many that the variety of epithelium revealed by the microscope in urinary examinations throws but little light on the location of the disease, I am firmly convinced that in the hands of an expert pathologist it is a most important aid.

Bladder irritability is distinguished from chronic cystitis in the same way as from acute cystitis, by the lack of pus in the urine. This applies as well to any condition resembling cystitis dependent upon nervous lesions, or functional affections.

Method of Examining a Patient.—In examining a patient with urinary symptoms we must

never jump hastily to the conclusion, from the history of frequency and pain, that cystitis is present, but should go into each case systematically. It is well to do this in two visits between which the patient's urine can be examined, and a urinary antiseptic given. In the office and the clinic the order is as follows: First visit: Palpate the kidney. Percuss and palpate the suprapubic region. Examine the external genitals, and then by rectum the internal genitals, the prostate and the seminal vesicles. At the same time the bladder can be palpated, although little can be made out as a rule in this way, except in case of stone or tumor. The urine is then taken for analysis, and the patient put on salol, 5 grains every four hours, or urotropin 7-8 grains, three times a day. Second visit: On the next visit, with a knowledge of the condition of the kidneys, bladder and external and internal genitals, as well as can be determined by palpation of the different organs and the analysis of the urine, we are better able to examine the urethra and bladder understandingly. The urethra is examined by *bougie à boule* for stricture, and the bladder with the stone-searcher and cystoscope, if advisable. The urethroscope is rarely used, except where a chronic discharge, which we are desirous of locating, is present.

Individual Consideration of the Different Cases.

(*1*) *Chronic Cystitis from Urethral Extension.*—This is either the remains of an acute attack of cystitis following an acute attack of gonorrhea, or else it is due to slow extension from a chronic posterior urethritis. It more frequently occurs, therefore, in young men with a previous history of urethritis, associated with pain in the neck of the bladder and frequency of urination. In this condition the frequency of urination is generally but slightly increased, excepting after excesses of eating, drinking or coitus, or exposure to cold or wet, when there is an exacerbation lasting for a number of days with a gradual return of the former condition.

(*2*) *Chronic Cystitis Due to Stricture.*—In this condition the patient is generally a man thirty to forty-five years of age, with a history of numerous attacks of urethritis running a chronic course. He probably has a gleet, a twisted stream, complains of frequency of urination, especially during the day, passes a small stream with perhaps a dribbling afterward, and he may have had one or more attacks of retention. Here a urethral examination shows a stricture, usually in the deep urethra.

(*3*) *Chronic Cystitis Due to Prostatic Hypertrophy.*—In this case the patient is from fifty to seventy-five years of age with perhaps no gonorrheal history or, if he had such trouble, it occurred many years ago. He has noticed for some time a desire to pass urine with increased frequency, especially at night. Sometimes his stream comes with a certain amount of hesitancy; he may even have had attacks of retention. He suffers considerable pain and burning in the neck of the bladder, especially after finishing the act. Examination shows quite an amount of residual urine in the bladder. The urethra is found to be elongated and rectal touch shows a prostate of increased size. If a cystoscope is used, the uneven edge of an enlarged prostate is noticed at the vesical neck.

(*4*) *Chronic Cystitis Due to Tumor.*—Here the patient is also fifty or over. He gives a history of hemorrhage of the bladder recurring with increased frequency, not dependent upon anything in particular and sometimes taking place during sleep, the blood being mixed with the urine, in clots, or coming out free after urination. An examination of the urine would often show much blood and tissue elements, fragments of tumors. The cystoscope will show a tumor, pedunculated or sessile, growing from the wall of the bladder.

(*5*) *Chronic Cystitis Due to Stone.*—In this case the patient may be of any sex, or any age. There will be a history of frequency of urination lasting for some months, or years, and pain in the region of the bladder, which in the male perhaps shoots into the testes. The frequency and pain are more active during the day, when the patient is up and about, especially when riding, or being jolted or jarred. The stream of urine will often stop suddenly during micturition, causing pain and tenesmus which will be relieved by change of position or by waiting awhile, when the urine will again begin to flow. Brick-dust deposit may be noticed at times in the chamber, or at intervals there may be colicky attacks originating in the loins and running down into the pelvis. In these cases the stone will be detected by the searcher, or seen on cystoscopic examination.

(*6*) *Tubercular Cystitis.*—This may occur in either sex, usually between the ages of eighteen and thirty years. The patient may never have had any venereal disease. The first symptom noticed is frequency of urination followed later by pain in the bladder and tenesmus. These two symptoms increase in severity both night and day, so that often the patient is obliged to urinate every few minutes during the twenty-four hours without obtaining much relief. These cases very often have a history of incontinence of urine during childhood, especially at night. They may have been very delicate, suffered from frequent coughs, or had abscesses in the neck, or some affection of the joints. The lungs may be affected, or there may be a family history of phthisis. In the male a rectal examination may reveal tubercular nodes of the epididymis, prostate or vesicles. The urine, in addition to the other signs of cystitis will show tubercle bacilli, or, if cystoscopy is performed, small tubercular deposits or ulcers may be seen in the bladder-wall. In cases of cystitis in which none of the other causes can be established it is probable that it is of tubercular origin.

Treatment of Acute Cystitis.—In this condi-

tion rest in the recumbent position is most essential. Hot sitz baths are of the greatest service, as by determining the blood to the periphery they diminish the congestion in the bladder, thus causing the inflammation to subside. They should be given twice a day as hot as the patient can conveniently stand. Hot rectal douches of saline solution are also of benefit, and can be given by means of the rectal tube, preferably the one known as the rectogenital variety made by Reynders & Co., of this city. The hotter these irrigations are given the more beneficial they seem to be, and the degree of heat which a patient can stand is surprising. The use of hot water in the rectum seems to alleviate the inflammation when the degree of heat is such that the hand can hardly be placed in the vessel. The temperature usually used is from 110 to 120° F. These hot rectal douches can be taken by the patient while in the hot sitz bath, or they can be taken independently of it.

The patient should take internally diluents of an alkaline nature, such as the potash salts; mild urinary antiseptics, such as the salicylates or benzoates, and antispasmodics, as belladonna, hyoscyamus or codeine. Of the urinary antiseptics, probably the benzoate of soda, 45 grains, salicylate of soda, 60 grains, or salol, 30 grains, a day, in divided doses, are the most efficacious. Of the antispasmodics, tincture of belladonna, 8 to 10 minims, tincture of hyoscyamus, 15 to 30 minims, codeine, ¼ to 1 grain, or morphine, ⅛ grain to ¼ grain, each to be given three times a day. These can be given combined with the diluents and urinary antiseptics or singly, as preferred. Very often the spasm and pain at the neck of the bladder are so intense that it is better to give the antispasmodics in the form of a suppository, especially at night, in order to allow the patient to obtain some rest. In this case the suppository should be made of ¼ grain each of morphine and the extract of belladonna in cacao butter.

If the urethra is not too sensitive, bladder irrigations through the meatus by hydrostatic pressure, according to the Janet method should be used. Of these, in the acute condition, permanganate of potash is probably the best, beginning with a strength of about 1 to 4000 and increasing it slowly until as high as 1 to 1000 is used. It will usually take a week of daily irrigations to reach this latter strength, increasing by easy stages. If the permanganate of potash is not efficacious, a solution of nitrate of silver may be used, beginning at 1 to 16,000 and increasing gradually to as high as 1 to 3000 or 1 to 4000. Boric acid or boroglycerine, a tablespoonful to the pint, is also of value.

Sometimes when the patient's bladder is very intolerant and about one ounce or more of fluid causes the patient sufficient distress to force him to urinate, it is better to give instillations of nitrate of silver by means of the deep urethral syringe until sufficient tolerance is established to allow the irrigation to be given, as in such a case the posterior urethra is also generally acutely inflamed. In giving these instillations it is well to begin with the strength of one grain to the ounce and increase up to ten grains if necessary. From five to ten minims of such a solution should be instilled at each sitting, and generally every other day is sufficiently frequent for such a treatment. It is surprising how much relief so strong a solution will give when applied to the very acutely inflamed membrane of the vesical neck.

Treatment of Chronic Cystitis.—In cases of chronic cystitis two conditions confront us, the cystitis and the cause. In all acute exacerbations of chronic cystitis the disease should be treated on the same lines as the acute variety already referred to. Most cases of chronic cystitis will improve if put to bed and given hot sitz baths or hot rectal irrigations, together with urinary antiseptics and large quantities of water internally.

Of urinary antiseptics those already mentioned are useful, also the oil of wintergreen and the oil of eucalyptus; but when the urine is alkaline, as is usual in obstructive cystitis, nothing equals urotropin in 7-8 grain doses every three to four hours. These measures, however, are merely palliative and no permanent cure can be effected except by local treatment. In every case great benefit will follow a systematized course of bladder irrigation, either by hydrostatic pressure or by the catheter and hand-syringe. The choice of means will naturally be decided by the consideration of convenience, and in this regard the latter method frequently offers more points in its favor. But, just as in acute cystitis, it is not advisable to pass any instrument into the bladder, so in cases of chronic cystitis in which the symptoms are very acute, as they sometimes are, especially in tuberculosis and stone, it would be unwise to attempt this procedure. In washing out the bladder by either means, simple boracic acid solution may first be used, or even saline solution or sterilized water, followed at intervals by solutions of permanganate of potash or nitrate of silver in the strength already mentioned.

Before proceeding to speak of the treatment of the different varieties of chronic cystitis, it might be well to say a word on the subject of prophylaxis. As a matter of prophylaxis, great care should be taken in keeping instruments clean. This applies as well to those used in examination as to those used in treatment. The most frequent instrumentation is used in cases of obstructive cystitis in which we are endeavoring to dilate a stricture, or relieve a retention, or to break a patient into catheter life. All hollow instruments should be flushed after use. As to sterilization, briefly, all purely metal and all soft rubber instruments may be sterilized by five minutes' boiling. Gum elastic and woven catheters, as well as all other instruments, may be sterilized by subjecting them to the formaldehyde vapor generated by means of the formalin pastiles and lamp in a Schering-Glatz sterilizer.

Treatment of Cystitis Due to Extension.—This consists chiefly of irrigation from the meatus by hydrostatic pressure with a solution of nitrate of silver, 1 to 2000 to 1 to 4000. The bladder having been filled with the solution, the patient empties it in the natural way, and the process is repeated once or twice at each treatment, if deemed advisable. It is usual to give one of the urinary antiseptics, and, if there be much tenesmus, hyoscyamus or belladonna.

Treatment of Cystitis Due to Stricture.—This should be directed to the palliation of the symptoms pending the removal of the cause. The restoration of the urethra to its normal caliber throughout will do away with the congestion produced by the increased effort on the part of the bladder to expel its contents, and, with the removal of this predisposing cause, we make appreciable gains in our attack on the disease. Whenever the stricture is capable of dilatation this should be brought about by means of sounds, or dilators. Of the latter the Oberländer is the most practical, the least cumbersome and the least complicated. As it has the same shape as a sound, it can be introduced readily into the urethra and the stricture can be dilated one or more degrees at each sitting, and by the aid of this one instrument we may accomplish the same result as by a set of sounds. The bladder should be washed out after each dilatation by the hydrostatic method with one of the antiseptic solutions already mentioned. Internal antiseptics should be used continuously throughout a course of dilatation, and the instrumental treatment should not be given oftener than twice a week.

If the stricture will not dilate and is so small as to give rise to considerable back pressure, it should be cut lest the ureters and the kidneys become involved. If it is situated in the anterior portion and will admit an Otis urethrotome, the cutting should be done by means of this instrument. As a rule, however, strictures that give rise to cystitis are small ones, situated in the deep urethra where this instrument ought not to be used. In these cases, if a guide can be passed, the Maisonneuve urethrotome should be employed, or an external urethrotomy performed, upon a grooved guide. When no guide can be passed into the bladder through the urethra the perineal cannula guide will be found of great assistance in the external operation.

Personally I favor the external urethrotomy, with bladder drainage for a few days if but one method is to be employed, as in operating with the Maisonneuve we cut in a very important part of the canal where we may have a serious extravasation, or a septic process started by the absorption of foul urine or urethral discharge. The ideal operation I consider to be internal urethrotomy by the Maisonneuve accompanied by an external urethrotomy, as the foul urine is thus switched off from the deep urethra by means of the tube, and the frequent irrigation which we give the urethra tends to keep it as clean and aseptic as possible. Previous to such an operation the patient should be kept in bed, should drink large quantities of water, and should receive internal antiseptics and hot sitz baths. The same treatment with the exception of the sitz baths should be continued after the operation, and the drainage of the bladder through the tube in the perineal wound should be kept up for from one to three weeks. Sounds should be passed every other day until the wound is closed and bladder irrigation given until the cystitis is cured.

Treatment of Cystitis Due to Prostatic Hypertrophy.—Many methods have been devised for overcoming obstruction at the bladder outlet, but at present they have been sifted down to two, or perhaps three, operative procedures, *i.e.*, enucleation, the Bottini operation, and the formation of a permanent fistula. In patients with good kidneys and heart, in whom the prostate is large and has a fibroid feel, the best remedy is enucleation. This can be done through the bladder, the perineum, or both. In patients in whom the enlargement is chiefly confined to the third lobe, and in whom the rest of the gland as felt through the rectum appears but little enlarged, although very much indurated, enucleation cannot be performed and the Bottini operation commends itself. By this procedure furrows are burned through the impediment, allowing the emptying of the bladder, and the blood-supply is cut off to such an extent by the searing process that atrophy of the gland takes place. When enucleation and the Bottini operation have proved to be of no avail a permanent suprapubic fistula may be established for the purpose of drainage.

Treatment of Cystitis Due to Stone.—The stone should be crushed by the operation of lithoplaxy and the particles removed through the evacuator, although in this country suprapubic lithotomy seems to be gaining favor. This is due, in a measure, to the fact that vesical calculus is so rare here that surgeons do not operate often enough to become expert in lithoplaxy as in countries in which this affection is common. When the cause of the congestion has been removed the cystitis may be cured by the methods already described.

Treatment of Cystitis Due to Tumor.—This condition is somewhat rare. The cystitis is secondary to the congestion due to the amount of blood sent to the bladder-wall to nourish the neoplasm. In almost every case the proper procedure is a suprapubic cystotomy, the growth to be removed if pedunculated by the scissors, if sessile, by the curette and its base cauterized.

Malignant growths are sometimes excised, but this operation presents a large death-rate, and even when it is successful recurrence usually takes place, therefore, in case the urethra is not of sufficient caliber for drainage, palliative treatment by means of a permanent suprapubic fistula is the best that can be done for this condition.

Treatment of Cystitis Due to Tuberculosis.—In the treatment of tubercular cystitis, the practitioner encounters a condition that taxes all the resources at his command and he errs, as a rule,

on the side of too much, rather than too little, treatment. In other words, it often happens that the more you treat the patient locally for his cystitis, the worse the condition becomes. It is, therefore, necessary to proceed cautiously in the treatment of this form of bladder inflammation, and, above all, is it important to improve the general condition of the patient as much as possible. If we were to treat patients suffering from tubercular cystitis along the same lines as pulmonary cases, namely, by sending them away to lead an open-air life under conditions that would improve their nutrition to the utmost, the condition would be much more rapidly improved or cured than by anything that could be done by the ablest specialist of the period.

Numerous remedies have been recommended by different authorities for the treatment of this form of cystitis, and naturally every practitioner who encounters this rebellious trouble grasps at anything that offers the probability of a cure. Guyon at one time advocated the use of intravesical injections of bichloride of mercury, 1 to 10,000, and since then many have been following his advice, but such a solution will rarely cure this disease, while it usually produces an irritation that is almost unbearable.

Nitrate of silver and permanganate of potassium have the same effect. Boric acid and boroglycerine irritate less, but do not seem to possess the power to ameliorate the disease. Recently iodoform injections have been advocated, and the procedure would seem to be founded on a logical basis. Three of four ounces of a five-per-cent. solution of iodoform in liquid vaseline are injected into the bladder every two or three days, the patient being instructed to watch the stream when he urinates and stop the flow just as soon as the oil appears. This forms a permanent iodoform dressing of the bladder-wall, and in the hands of some of the French surgeons is said to have met with gratifying results.

Personally, I have had better results with borolyptol in this class of cases than with any other remedy which I have employed. This seems to have a powerful germicidal effect, while the fact that it does not irritate the bladder renders it pleasant to the patient. It is used in the strength of from 1 in 8 to 1 in 16 in irrigations by the hydrostatic method. After a few irrigations at the office the patient will be able to use it every night at home. I have one patient now under observation who suffered for a number of years from a most aggravating frequency of urination accompanied by pain, dependent upon a tubercular cystitis. Under this treatment the urine has cleared up, the tubercle bacilli have disappeared and the patient can hold his urine from seven to nine hours at night and from four to six hours during the day.

Internally, in connection with any local treatment, an antispasmodic and an internal antiseptic should be used as a palliative measure; it is wonderful how much relief may be given to the patient by this means, even although pus remain in the urine and the tubercle bacilli still be found. One patient has been coming to me for three months who was entirely relieved of his disagreeable subjective symptoms by a mixture containing 10 minims of the tincture of belladonna, 15 grains of benzoate of soda, and oil of gaultheria up to one drachm, t.i.d., although not until he was put on the borolyptol irrigation did the pus and tubercle bacilli in the urine diminish to any marked degree. The effect of the palliative internal medication is worthy of notice, in view of the fact that he had suffered for fourteen years, and had been under the care of many different physicians without relief, having most probably been overtreated by too much instrumentation and too frequent or too irritating irrigations.

63 West Fifty-fourth Street.

CLINICAL LECTURE.

HYPNOTISM.

By F. X. DERCUM, M.D.,
OF PHILADELPHIA;
CLINICAL PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM IN JEFFERSON MEDICAL COLLEGE.

A GREAT deal of unnecessary mystery attaches to the subject of hypnotism. To the minds of the laity the name suggests something weird and uncanny and this statement may even be made of a large number of physicians. As we make a demonstration of its use and explain the principles upon which it is based, I think you will agree with me that there is nothing strange about it. The fact of hypnotism cannot be disputed. It is well known that animals, such as birds, rabbits, etc., are easily hypnotized by forcibly attracting their attention; and by drawing a line on the floor or ground in front of them they will remain in a fixed position. The fact is also true as regards human beings, the subjects capable of being hypnotized belonging to the great class of neurotics, many of the symptoms of which these people complain resembling those of hysteria.

The hypnotic state is usually divided into three stages. First, there is the stage of catalepsy, or sleep, in which there is muscular relaxation. Second, the stage of lethargy, in which the sleep is deeper, and instead of muscular rigidity, the head or limbs of the patient remaining in whatever position they may be placed. Third, the stage of somnambulism, or stage of automatic movements.

Because I hypnotize a subject before you I do not wish it to be understood that I am an exponent of the practice or that I wish you to follow it in your future work. On the other hand, you should use it only under very exceptional circumstances, and then with strict regard to the rules which will be subsequently laid down. The importance of hypnotism has been greatly exaggerated, both as to its medical aspects and by the public. The lay idea regarding it is obtained

largely from professional hypnotists and traveling pretenders with their more or less misleading exhibitions.

The field for the legitimate practice of hypnotism is an exceedingly limited one. I wish also to say that there may be an element of danger for the one who practises it. There is not only a suggestion to the patient but there is also an autosuggestion to the operator. Excessive study of hypnotism may lead to untoward results in some persons. We often meet with laymen or students who are studying hypnotism, or investigating its powers. These persons should remember that there is a certain amount of danger as regards their own mental stability—a danger which arises from their own increased susceptibility to involuntary autosuggestion.

As physicians, hypnotism interests us from two points of view: First, the explanation of its principles, and, second, the extent of its practical application. There are many theories explaining the induction of the hypnotic state, but the great bulk of them are metaphysical in character and have no practical value. The laity may be satisfied by such explanations, but they will not do for the medical man. He must have a rational, a physical, or a physiologic explanation of the subject. The explanation which I shall give is based upon the structure and workings of the nervous system itself and thus has an anatomic and physiologic basis.

To explain hypnotism we must first explain the physiology of natural sleep. The nerve-cell, with its processes or dendrites, makes up the unit of nervous tissue. These units, or neurones, bear various relations to each other at different times. There are some men, and I have for a long time been one of them, who think that these elements retain some of the mobility which they possess during embryonic life. Under certain conditions they change their relation to each other. Whether this change is a mechanical one or not makes but little difference, however, and does not influence the theory. They must change their physiologic relations in some way. I say this because there are some investigators who do not accept the neurone theory and hence not the physical changes mentioned. I still think the neurone theory of nerve-structure to be the correct one, but, as I have said, even this is not a necessary part of the explanation of sleep or hypnotism.

During the waking hours of the individual the various nerve-cells are in relation with each other, the dendrites being in contact or in physiologic relation with the collaterals or other processes of neighboring cells. In sleep the processes are retracted and the cells of the cortex, being separated, cannot discharge any function when in this condition. Many authorities regard this as the probable explanation of sleep. In hypnotism, the sleep induced is a partial one, but it is the same intrinsically as ordinary sleep. In lethargy or catalepsy or somnambulism the sleep is only partial. The principle followed in the induction of hypnotism is to suggest sleep and to induce it by fatigue of some part of the body—the ordinary way in which physiologic sleep comes. To do this it is common to select some muscles that are easily fatigued and of these the ocular muscles are perhaps the best. As a common expedient in tiring the ocular muscles, the patient is asked to look intently at some object, preferably a bright one. This object is then brought nearer and nearer to the patient's eyes, thus causing greater effort of convergence to be exerted, until the focusing becomes very difficult and fatigue of the muscles is induced. When this stage of fatigue is reached the pupils dilate and the eyes are seen to diverge instead of converging as before. If, when the patient is in this state, sleep is suggested to his mind, the latter follows very readily. With the patient in a partial sleep and with the eyes closed no information regarding the outside world or the operator can be obtained from the sense of sight. They hear only what the operator says and practically by the avenue of the ear alone suggestions reach the cortex. The skin and muscles may have a small part in transmitting suggestions, but it is mainly by the ears that this is possible. If, then, suggestions are made to the patient, they are accepted as they are made. All the other senses excepting hearing being shut off, the impressions on the cortex come by way of the ear and are not corrected or contradicted by sight or the other senses. There is no readjustment of statements heard by what is seen, and, therefore, the patient believes whatever the operator suggests.

The patient whom I bring before you is a young woman who has consulted many physicians. Within the last year she has consulted the great exponents of hypnotism in London, France, Germany, and Vienna. In the last place Professor Benedict induced hypnotic sleep by magnetism, a powerful horseshoe magnet being placed over the occipital region. When this young woman first came to me she complained of a pain in the shoulder. This was at first regarded as rheumatic in character and was treated as such, but antirheumatic remedies proved of no avail. An examination revealed the presence of numerous stigmata of hysteria. She then told of being cured of similar symptoms by hypnotism, and I tried that with the result that the pain was relieved and never returned again in the shoulder. But other portions of the body are affected and symptoms appear from time to time in a continuous cycle, being relieved by hypnotic suggestion, only to reappear after a time in other places. The patient now has headache and pain in the eyes, although the symptoms are more general than local in character.

Anything will do to attract the eyes of the patient in order to induce fatigue of the ocular muscles. I use the bright handle of an instrument, but my finger would do just as well, as sleep is readily induced in this subject. The patient is now in a condition of partial sleep, which is attended by muscular relaxation. Cata-

lepsy and somnambulism could be readily induced and the patient made to do various automatic acts for our amusement, but I leave such tricks for the professional hypnotist, as they have no part in a medical clinic. Only this state of partial sleep is used for medical purposes, nothing being gained by catalepsy or somnambulism, although they are readily induced.

When use is made of the hypnotic state, we treat the symptoms complained of just as the physician treats symptoms in other ways. I take the patient's hand in mine, as I always do when I practise hypnotism (although it is only in exceptional cases that I have recourse to this practice), in order to reinforce the suggestion. I then say to her that when she awakens she will have no pain or headache and that she will feel buoyant and happy. This should be repeated several times, perhaps ten or more, and should be stated as impressively as possible and coupled with the statement that the pain will never return again.

Shall we now awaken the patient? Not yet, for there are certain precautions to be taken. The suggestion should be made that no one can hypnotize the patient unless she be willing that it should be done. This is especially necessary in patients who have been hypnotized often. This young woman was riding in a street-car at one time and when one of the passengers stared at her she went to sleep. I made the suggestion that she could not be hypnotized unless she were willing, but she remembered the incident in the car and was still fearful. I then hypnotized her again and said that no one but myself could hypnotize her in the future. The incident was forgotten and sometime afterward a young French physician who had made a study of hypnotism was visiting the clinic. He tried repeatedly to hypnotize this patient but failed. I then remembered what I had said and on making a trial sleep was readily induced. A suggestion once made may last for a long time. Others have tried to hypnotize this patient but have failed because my suggestion still remains, it having never been removed. The hypnotists she visited when abroad were also unsuccessful. In Vienna, Professor Benedict was probably successful in inducing sleep by magnetism, because the suggestion I made did not include that method of inducing the hypnotic state.

In addition to the disappearing of the symptoms and the fact that no one can hypnotize her unless she be willing, a third suggestion should be made to the patient before she is awakened. That is the statement that she will feel well and comfortable after she is over the sleep and will not be tired from the fatigue induced. This is necessary because the treatment is more or less exhausting.

How shall we awaken the patient? This can be done as from normal sleep by loud talking, clapping the hands, etc., if the sleep has been slight. If it has been a profound one the patient cannot be aroused so easily. But in either case she can be awakened by suggestion, which is the better way of doing. I will make the suggestion that this patient will awaken in one minute. Any time could be given, as five or ten minutes. It is curious how the actual time of awakening in these cases corresponds to the time suggested. The patient awakens, says she feels a little dizzy, but better than she did before. As she becomes more thoroughly roused she feels better, and, finally, after a minute or two says she feels all right again and that the disagreeable symptoms from which she had suffered have disappeared.

There are certain important things to remember if hypnotism is practised at all. First, there should always be present witnesses of the same sex as the patient. This is as important, or even more so, as when ether or other anesthetic is being given. A nurse, or, still better, friends of the patient should be by in all instances. The reputation of a physician could readily be damaged if witnesses were not present. Second, if hypnotism is ever used, it must be for plain and obvious purposes and in proper cases. The physician should be honest with his patients and tell them what the process is and that the purpose is to relieve the symptoms. Third, it should be remembered that the hypnotic state is induced by fatigue and that if it is prolonged or carried to a profound degree the patient may suffer severely from exhaustion. This patient is of a hysteroneurasthenic make-up and the hypnotic state is induced with extreme facility. The state of catalepsy may be induced without suggestion, the same also being true of somnambulism. Sometimes there is diuresis after a treatment or the solids of the urine may be remarkably diminished, showing that the process has interfered in some way with tissue metabolism. Knowing this the physician must remember, if he use hypnotism at all, that he is using an expedient which may be productive of harm instead of good to his patient.

Different individuals are susceptible to hypnotism in varying degrees. In some, the hypnotic state is easily induced, while in others attempts will fail entirely. A great deal depends upon the persistence of the physician. Some operators are very persistent in certain cases; for instance, trying for three or four months with one patient and finally being successful.

And now having discussed the theory of hypnotism and the method and precautions to be observed in its employment, we come to the question of what practical value it is to the physician. In my experience it is of very little value and has a very subordinate part in therapeutics. It may occasionally cause a permanent disappearance of the symptoms complained of by the patient, but more often they reappear. The pathologic cause, if present, does not disappear. If symptoms do disappear, others often come in their places as in the subject before us. There is a certain pleasurable sensation in the hypnotic sleep for these subjects. It shuts out all of the outside world and thoughts of their troubles and thus acts to them as a stimulant. They come back week after

week and thus the hypnotic habit is formed.

Hypnotism is practically limited in its scope to hysterical and neurasthenic patients. In others, where there is an actual pathologic lesion, suggestion can have no influence in its cure. And, further, I find I can accomplish with hysterical patients as much, and even more, by suggestion without hypnotism than with it, hence I rarely employ it. If the physician always acts with a certain reserve and dignity toward his patients he will have great power over them, especially so in the case of neurasthenic and hysterical people. They will watch every movement and look of the physician and if he will say impressively that their headache or other symptom will be better in a little while, the symptom is often relieved. If such patients are restless and excited and the physician gives them a little water or starch or other harmless substance and tells them that they will sleep, they will often do so. This method is much preferable to the use of hypnotism. All other rational means of treatment should be first used before recourse is had to hypnotism, and then it should be used only under the precautions named and to a limited degree. Some of you may never see a case in your lives that needs hypnotic suggestion. It is not a pleasant thing for a physician to acquire the reputation of being a hypnotist. It attracts attention because the public does not understand its principles, and to them there is something uncanny and unpleasant about it. I hope none of you will ever practise it unless under the most exceptional circumstances.

CLINICAL MEMORANDUM.

A CASE OF SPONTANEOUS RUPTURE OF THE UTERUS.

By BRADFORD WOODBRIDGE, M.D.,
OF ROCKLIN, CALIFORNIA.

Rupture of the uterus late in gestation from a blow or other injury, or during labor either from excessive contractions or operative manipulation, is an uncommon event, its frequency from all causes, according to Etheridge[1] being one in four thousand labors. Of extreme rarity must be cases such as the one I report, in which in an apparently healthy young woman before the advent of labor and without history of trauma or premonitory symptoms, this accident took place.

Mrs. S., an American, aged twenty-eight years, the mother of one child, was first seen by me on the morning of October 18, 1899. According to her statement her confinement had been due about a week, as she had ceased to menstruate January 27, 1899. For an hour or more she had been having occasional slight pains in the back and abdomen, although she herself doubted whether they were severe enough to have any significance. An examination showed no dilatation of the os, and the patient was told that it was impossible at that time to determine whether the pains were indicative of the onset of labor.

[1] Jewett's Practice of Obstetrics.

During the period of gestation the woman had been exceptionally well. In her previous confinement, two years before, labor had been slow, and delivery had been effected with the forceps. At that time, a few days before her accouchement, she had received a blow upon the abdomen while playing with a child, and she believed labor to have been somewhat premature from that cause.

Three hours after I had seen her she went into a condition of sudden collapse. Examination of the abdomen showed an evenly rounded contour, the fetal protuberances having disappeared. Pressure gave a "boggy feel," which had not previously been detected. The fetal heart-beat could not be distinguished. Digital examination revealed no change in the condition of the os. A tentative diagnosis of "accidental concealed hemorrhage" was made. Two consultants were called, one a surgeon of more than local reputation, and the other an obstetrician of wide experience. It was deemed best to postpone active measures until the patient had rallied in some degree from the condition of collapse. Free stimulation, consisting chiefly of injections of normal salt solution, was employed with slight temporary benefit. All response to the remedies failed, however, and the woman died about thirty hours after the onset of the trouble.

The abdomen was opened two hours after death. A thick layer of clotted blood was found between the abdominal wall and the uterus. Across the top of the uterus there extended a jagged transverse tear. The left hand and shoulder of the child projected through the rent into the abdominal cavity, while the rest of the body was grasped tightly by the uterine muscle, which had contracted like a tissue of rubber.

In speculating as to the cause of the rupture it is to be remembered that the woman had received a blow in the pregnant uterus two years before, severe enough, she believed, to have hastened labor. As a result there may have been a weakening of the uterine muscle at the point of injury. It is also possible that the contractions were more intense than was indicated by the severity of the pain and the condition of the os. An immediate laparotomy might not have saved the patient, but such an operation would have been the sequence of a precise diagnosis.

MEDICAL PROGRESS.

Normal Prophylactic Appendectomy. — The *Medical Review* (March 17, 1900) has recently obtained the opinions of eighty-nine eminent surgeons throughout this country with reference to the advisability of the above operation being done upon children as a routine measure. Only one surgeon, Dr. Pollak, gives unqualified assent, three more approving with some degree of reservation. All agree that a mortality of at least one-half of one per cent. must be expected in the most skilful hands, and if it were so com-

monly performed the death-rate would be greatly increased, owing to the lack of skill of the operators and the unfavorable surroundings in many cases. The consensus of opinion seems to be that since only about one per cent. of people ever have appendicitis, it would be extremely bad surgery to subject the other ninety-nine to a useless operation, which is not without danger and which is so often followed by post-operative symptoms of adhesions and even hernia. Several advised the removal of a normal appendix while another abdominal operation is being done, provided the patient is not subjected to any further risk. Many strongly urge that the advancement in the treatment of this condition should be made along the lines of an early diagnosis, when an operation can be performed with very little danger and the mortality reduced to a figure not much above that for normal appendectomy. It is the verdict, therefore, of American surgery that normal prophylactic appendectomy is a hope almost barrenless of possibility.

Mammary Cancer.—W. M. Banks (*Lancet*, March 24, 1900) says there are certain dangerous delusions in the mind of the laity and many of the profession concerning cancer of the breast, which lead them to defer consulting the surgeon until the best time for operating has passed. These errors are mentioned: Heredity seems a prominent causative factor in the mind of the laity; pain is thought to be an essential symptom of cancer, but is, as a rule, entirely absent in the early stages of the disease, and the lump is usually accidentally discovered; cachexia, even in a large portion of the medical mind, is considered necessary to the diagnosis, whereas it occurs late in the disease from pain, fetid discharge, septic absorption, insomnia and mental distress; early in cancer the patients are very frequently well-nourished, ruddy individuals. In internal cancers cachexia may very well be present when the trouble is first diagnosticated; nipple-retraction and skin-adhesion are familiar only to the profession; retraction occurs only when the growth is immediately under the nipple; adhesion of the skin to a cancer is of the "pigskin" variety, and is quite characteristic. Chronic mastitis is not infrequently mistaken for cancer. It is more apt to occur in comparatively spare, childless women, and after a time causes the breast to resemble a hard, flat cake, with harder knobs here and there. In these cases, skin-adhesion is rare and when present not of "pigskin" type, and glandular involvement is not present. Deep-seated chronic abscess surrounded by dense inflammatory tissue is very deceptive. Skin-adhesions when present do not cause pigskin dimpling. Exploration is the only certain means of differentiating. The same points are true concerning a small fibro-adenoma, a small, very tight, deep-seated cyst. In order to avoid error in diagnosis, he never removes a breast without first incising the tumor or exploring it with trocar and cannula. A breast tumor should be examined in three ways: The surgeon should first stand behind the patient and reach round to the breast, as this position gives his tactile sense its best advantage; then, from in front he examines the patient sitting and, finally, lying down. The examinations in these different postures develop all the tumor's features. When the diagnosis is once made, extirpation of the breast and axillary contents is imperative.

Cause of Cancer.—An interesting contribution to our knowledge of the etiology of cancer is given by A. Adamkiewicz (*Klin. therap. Woch.*, March 18, 1900). This author holds to the parasitic theory and considers the cancer-cell to be not a typical epithelium, but a species of coccidia which infects those parts of the body most closely in contact with the outer world. Several instances are quoted in which the mere sting of an insect was followed by epithelioma of full malignancy and in which irritation or diminished resistance of the parts involved could not explain the lesion. The fact that gastric and intestinal cancer is endemic in certain parts of France where stagnant water is used in the manufacture of cider, seems to corroborate this theory.

Addison's Disease; Autopsy.—William Fitch Cheney (*Phila. Med. Jour.*, March 24, 1900) reports a case of this disease with autopsy. The the patient was a large robust man, weighing 230 had always been well with the exception of an attack of pleurisy with effusion. Six months before he came under the observation of the writer, the patient was a large robust man, weighing 230 pounds. At that time the man began to feel tired and his appetite began to fail. The weariness increased and his appetite grew poorer until, when he came to the hospital six months later, he could scarcely crawl about, and seemed to have a positive aversion to food. This weariness increased to exhaustion so great that he could scarcely sit up in bed. In the six months previous to entering the hospital he lost sixty pounds and weighed at the time of reporting 170 pounds. At about the same time that the patient began to feel tired, he noticed a peculiar bronze-like discoloration of the skin. This appeared first on the forearms and legs, but gradually extended until the whole body was involved. With the discoloration there was itching, especially marked where the pigmentation was deepest, on the extensor surfaces of the forearms and legs. Here and there in the darkest areas were numerous small brownish-black spots, the size of pin-heads, resembling moles. The conjunctivæ and the mucous membrane of the mouth were not pigmented. For a number of weeks before the writer saw him the patient suffered from very violent palpitation of the heart and dyspnea, following any overexertion. The patient slept well, the bowels were regular, and there was no stomach disturbance except the progressive loss of appetite. The general physical examination was negative, except that the action of the heart was exceedingly weak.

There were no murmurs to be heard over any of the valves, but the tones were exceedingly weak and distant. The pulse was remarkably lacking in volume, in force, and in tension, and at times it could not be found at all at the wrist; its average rate was 90. By means of an injection of tuberculin, and the typical reaction which followed, it was decided that the affection of the suprarenals was tuberculous. At the autopsy the adrenals were both found to be enlarged, and their cut surfaces showed a number of large caseous areas surrounded by grayish-white granulation tissue. Only a small area of normal adrenal tissue remained. The microscope showed diffuse caseation, with beginning calcification in the center. Dense scar-tissue surrounded the caseous areas. Tubercles were found in the liver and also one in the left lung.

Epilepsy; Its Etiology and Pathology.—After reviewing briefly the various theories of the causation and pathology of epilepsy, W. House (*Phila. Med. Jour.*, March 24, 1900), believing that "like causes produce like effects," compares the symptoms of epilepsy with those of diseases which produce or are accompanied by convulsive seizures, resembling more or less the seizures of epilepsy. These diseases are hysteria, tetany, the eclampsias, alcoholism, cerebral hemorrhage, and the apoplectiform and epileptiform convulsions of general paresis. The pathology of the three latter conditions is well known and in certain respects the lesions are of a similar nature. The symptoms of an epileptic seizure, of an epileptiform paretic convulsion, of an alcoholic convulsion, and of cerebral hemorrhage present a marked similarity, so much so that sometimes it is difficult to make a differential diagnosis. Symptoms of cerebral pressure are present in these three conditions and also in epilepsy. In the brain of an alcoholic there is an excessive quantity of cerebrospinal fluid, the ventricles are distended, the brain-substance drips with fluid, and the membranes are dropsical. This is called the "wet brain." In general paresis the ventricles are distended with fluid, there is an increased quantity of fluid in the subdural space, and the whole brain is surrounded with an excessive quantity of turbid cerebrospinal fluid. In both these condition the excessive fluid seems to the author to be the logical cause of the pressure symptoms recognized in convulsions from these diseases. House has witnessed the autopsies of five cases of status epilepticus, and in each instance there was found an excessive quantity of cerebrospinal fluid. Arguing from analogy, House is forced to the conviction that this increase in the quantity of cerebrospinal fluid must bear a causal relation to the convulsions of epilepsy. According to physiologic findings, if the cerebrospinal fluid be suddenly withdrawn, convulsions may ensue; if rapidly increased, coma may be produced. From observation of over two hundred epileptics, and comparing their symptoms with those of sixty alcoholics and those of a large number of paretics, from the findings in the above five autopsies, and from an analysis of recent literature he concludes that: (1) There is no record of pathologic findings which logically explain the symptoms of epilepsy. (2) An increase of cerebrospinal fluid would readily account for the seizures. In many instances it is analogous to the marked increase of fluid in the crania of alcoholics and paretics, and is not dissimilar in clinical effects to the more localized lesions of hemorrhage or abscess. (3) This fluid, physiologically subject to more or less variation in quantity from day to day, is fully capable of pathologic increase, and from analogy must bear exciting relation to the convulsion. (4) Its increase is probably gradual, and to this we may ascribe the auræ. (5) Its absorption probably begins with the third stage of the convulsion (relation and coma), and if this fails, repeated convulsions (staticus epilepticus) ensue. (6) Its superabundance may be due to lymphatic spasm, or to marked disturbance of equilibrium between lymphatic and general circulatory activity, which may be favored by heredity, toxemia, or any of the recognized predisposing causes. (7) This creed applies to the so-called idiopathic epilepsy, as distinguished from the convulsion of Jacksonian epilepsy, although even in such cases this condition will help to explain some otherwise unexplainable symptoms.

Hydrogen Peroxide in Uterine Hemorrhage.—Applied locally this remedy, says R. Platon (*Annales de gyn. et d'obstét.*, Jan., 1900), is antiseptic, deodorant and hemostatic. It causes little or no local irritation, no erythema and no toxic symptoms. It may be employed as a rapid hemostatic in the ear, the mouth or the nose; and of late has been most successful in stopping uterine hemorrhage, when ergot, tampons, soaked in iron solutions, and hot intravaginal douches had not any effect. The peroxide may be applied by tampon, or be injected directly into the uterine cavity.

Muscular Rheumatism.—The diagnosis of muscular rheumatism is a most favorite one among many physicians when an ailment accompanied by pain is found, for which no cause can be discovered. A very interesting article on the pathology and treatment of this common condition is given by I. Adler (*Med. Record*, March 31, 1900). The usually accepted opinion is that the disease is one in which muscular pain is the prominent symptom, accompanied by functional disturbances and even obstinate contractions, but which depend on no structural lesions. The author, however, believes that the underlying cause of every case of muscular rheumatism is an inflammation, not necessarily confined to the muscle, but as far as the latter is concerned is an interstitial inflammation, or a myositis interstitialis. It may be mild in form and subside without much structural change of the muscle, or it may go on to a gradual degeneration of the muscle cells and a replacement fibrosis, leading to the formation of considerable masses of indurated fibrous tis-

sue. In muscular rheumatism the nearest joints usually suffer and the adjacent tissues may also be involved, such as the fasciæ, tendons, cellular tissue, and especially the nerves. Thus, a typical rheumatic neuritis may be caused in which an interstitial inflammatory process exists. Furthermore, these inflammatory conditions give physical signs which may be found in nearly every case in the form of circumscribed patches of swelling and infiltration. These may be located at the point of pain, but in some cases of lumbago, for instance, the pain will be referred to the whole lumbar region, and a careful search will reveal a small nodule or area which is very tender and from which the pain radiates in various directions, probably due in these cases to the involvement of the nerves. The degree of infiltration varies greatly and differences in consistency, elasticity and size are to be carefully noted, together with a comparison of the two sides. The clinical picture differs much. It may resemble an acute infectious disease with slight temperature, swelling, redness, tenderness and pain, or it may exist as a chronic affair, appearing at intervals in various and widely distant regions, or it may cling obstinately to one spot, occurring again and again; as the common lumbago, the rheumatic *caput obstipum* (stiff neck) or certain forms of intercostal pains. The author also believes that these conditions are not infrequently accompanied by endocarditis. Etiologically a strain is very important, and, although it may be the direct cause of an acute myositis, it usually acts by exciting an exacerbation of the chronic interstitial inflammation which already exists. Several reported cases of apparent cholecystitis or appendicitis were found to be acute myositis of the abdominal muscles. It is believed that rheumatic myositis is an infection caused, most probably, by cocci, still less virulent than in rheumatic arthritis. Their presence has not yet been proven, nor has their mode of invasion been found. For the acute cases, rest, ice-bags to the affected parts, and salol internally are indicated. After the acute stage these infiltrations demand careful attention and must be removed by local measures. Hot baths, electricity, gymnastics and iodides may improve the general health but do not remove the local lesion. Massage by an accomplished masseur is the most efficacious treatment, and is successful in nearly every instance. It is necessarily quite painful at first, but as the infiltrations are reduced the painfulness is gradually diminished. Where muscular cicatrization has occurred, excision must be employed. This has been done repeatedly with excellent results.

Acetonuria.—The most useful clinical test for acetone in the urine, according to Ronsse (*Annales de gyn. et d'obstét.*, March, 1900), is that of Lieben which is performed by adding a few drops of Lugol's solution to the first 10 c.c. obtained by distilling 400 c.c. of fresh urine, then adding sodium hydroxide solution until the brown color disappears. In the presence of acetone a milky precipitate of iodoform is produced, and may be recognized by its violet coloration with caustic soda and thymol, or by its yellow hexagonal cystals under the microscope. Acetone is found in small quantities in the urine normally, and it occurs pathologically in diabetes, cancer, phosphorus or chronic lead-poisoning, certain digestive troubles, hysteria, in prolonged fevers, the acute exanthemata, in eclampsia and during pregnancy. It is especially marked during prolonged labor, and many writers claim that it indicates death of the fetus, but in a study of fifty-three cases Ronsse finds that it has no such significance.

Electrical Treatment of Arthritis Deformans.—M. A. Cleaves (*N. Y. Med. Jour.*, March 31, 1900) reports two cases of rheumatoid arthritis which were markedly benefited by the use of electricity. In one case Franklinic electricity was employed with connective discharge from crown electrode for ten minutes, and with the brush electrode to the entire general surface, and especially upon the affected part to relieve pain and disability. In the other case a continuous current bath was given with the patient immersed in normal saline solution. An electromotive force of ten volts was used for ten minutes, followed by a sinusoidal current administered in the same way, full power of the alternator (1496 alternations to the second) for ten minutes. Attention is called to the fact that in both these cases the expenditure of energy was to the entire organization, with the purpose of setting up such nutritional changes as would result in relief from pain and improve the general health.

Treatment of Anal Fissure.—Fissure of the anus, according to I. Boas (*Revue d'obstét. et de gyn.*, Jan., 1900), may be successfully treated without operation, as follows: The patient is to remain in bed on fluid diet for one week, taking ten drops of tincture of opium three times a day. Absolute constipation being thus ensured, the fissure is sprinkled with iodoform or calomel, and is not touched with any antiseptic liquids. After eight days a large dose of castor oil is given and the patient told not to let his bowels move until the stools are liquid. Often the first defecation is quite painless, and the fissure is cured. The procedure may rarely have to be repeated.

Causation of Cancer.—J. Sawyer (*Lancet*, March 24, 1900) quotes statistics to the effect that mortality from cancer has doubled during the last thirty years in England and Wales. The consumption of food *per capita* has also increased, especially in meat foods. The upper middle classes who use meat in moderate quantity and well cooked do not show so great an increase in cancer as the great masses of people who eat excessively of meat usually none too well cooked. Therefore, he concludes that development of cancer is largely favored by increased use of food especially of the proteid type.

Perineal Prostatectomy.—P. J. Freyer (*Brit. Med. Jour.*, March 24, 1900) publishes a new method of perineal prostatectomy adapted to selected cases. First, a perineal section of the urethra is made and the left forefinger inserted into the bladder. From the posterior end of this wound a crescentic incision is made to the coccyx on either the right or left side of the anus, and the dissection carried up into the corresponding ischiorectal fossa. The finger in the bladder now presses the prostate down into the wound, the capsule of which is reflected and the necessary amount of hypertrophied tissue removed, care being taken to enter neither urethra nor bladder. A drainage-tube is fixed in the bladder, and the ischiorectal wound packed with gauze. The advantages of the method are: The preliminary urethrotomy allows a finger in the bladder and with another finger in the rectum the surgeon can make a careful complete examination; the bladder finger can hook the prostate down into the wound, thus facilitating the dissection; the capsule is easily reflected and the finger in the bladder allows the surgeon to feel the approach of the excising instruments to the bladder, and he can remove the whole growth, except a thin layer to support the mucous membrane, without entering the urinary tract and so infecting the deep ischiorectal wound. The perineal tube carries off the urine and so prevents it infecting the wound. The drawback is that the operation is limited in its application. Middle-lobe hypertrophy and a large prostate in a very fat person are not operable by this method, since the finger is not long enough to hook over the growth to depress it.

Uses of Hematogen.—Hematogenum siccum already has sufficiently proven its value in primary and secondary anemia, but J. A. Goldmann (*Klein. therap. Woch.*, March 18, 1900) finds it no less efficient in other chronic constitutional or infectious disorders characterized by disturbed nutrition and defective assimilation. In tuberculosis it can be well combined with antiphthisical remedies and even advanced cases have been seen to improve marvelously. In scrofulosis, rachitis and chronic catarrhal affections similar results were obtained. It is usually well taken plain, but can readily be given with other articles of food, such as cocoa.

Cardinal Sign of Colles' Fracture.—M. W. Ware (*Med. Record*, March 31, 1900) says that in 300 cases of Colles' fracture the much-talked-of silver-fork deformity was present in less than ten per cent. of cases, and its absence is therefore of little diagnostic significance. A better ground of diagnosis depends on certain fixed anatomical relations. The styloid of the radius is always at a lower level than the ulnar styloid. In ninety-five per cent. of Colles' fractures there is impaction, and as a necessary result the radius is shortened and the radical styloid rises to or above the level of the ulnar styloid. This sign is so constantly present as to be the cardinal pathognomonic sign of Colles' fracture and gives one a reliable guide for complete reduction. This diagnostic point is mentioned by few and emphasized by none of the works on fractures.

Albuminuria; Its Prognostic Value.—The mass of evidence from the autopsy-table shows conclusively that chronic nephritis exists and is the recognized cause of death in a large number of cases. A comparison of the histories of these cases and the autopsy findings shows that little reliance can be placed on mere urinary examination as a means of absolute diagnosis or prognosis of Bright's disease. It is acknowledged that chronic interstitial nephritis can exist without albumin, without casts, and without uremic symptoms. It is the experience of C. A. Tuttle (*Jour. Am. Med. Assoc.*, March 31, 1900) that albumin and casts, either hyalin or granular, or both, can exist in the urine and yet the health of the individual be unimpaired for years. The writer's experience leads him to believe: (1) That Bright's disease may exist without the ordinary urinary manifestations, *viz.*, albumin and casts. It may begin, run its course, and terminate fatally without at any time showing other urinary symptoms than continued low specific gravity or frequent micturition. There are also cases which show albumin and casts at one period, but these symptoms disappear and the patient has good health for an indefinite number of years. The writer cites a case in which the diagnosis of nephritis was based upon the edema and uremia, albumin and casts being found, and the diagnosis was confirmed by autopsy. In another case albumin was found in only one-third of the seventy-five examinations made during three months. (2) That positive urinary indications, *viz.*, albumin and casts, may be found in the normal urine and hence, do not necessarily mean Bright's disease. The writer has under observation seven cases of healthy individuals in whose urine albumin has existed from two to nine years, and one hale and hearty man who has had a considerable quantity of albumin in his urine for twenty years. (3) That, given a case of chronic Bright's disease attended with albuminuria, the fact of its presence, its constancy or its amount, has absolutely no prognostic significance. From observations of over one hundred cases the writer believes that the prognosis in chronic nephritis should be based on the amount of destruction of the renal parenchyma, but the amount of albumin in the urine is by no means indicative of such destruction. Moreover, there is nothing known as yet that serves as a measure of such destruction. Albumin may simply indicate a lesion of the glomerular filtering membrane, and other means must be found to ascertain its extent or gravity. Cheney cites a number of writers in support of these opinions of his.

Carcinoma at Sixteen.—J. H. Abram (*Jour. Path. and Bacteriol.*, Feb., 1900) reports a case of primary carcinoma involving the glomeruli of the kidney in a boy sixteen years of age. This condition he regards as almost unique, there being

but two cases on record resembling the author's. The character of the cells was such as to make him regard the tumor as having originated in the glomeruli and, possibly, associated with a persistence of the epithelium of the primitive renal tubule, thus supporting the Cohnheim embryonal origin of such new growths.

Treatment of Diabetes Mellitus.—G. D. Barney (*N. Y. Med. Jour.*, March 31, 1900) divides the treatment of diabetes into dietetic and medicinal. The object of the former is to exclude as far as possible all sugars from the regimen, but in some persons, especially those advanced in life, a more liberal diet seems to be far more beneficial. The diet-list should include soups, fish, poultry, game and meats, spinach, cabbage, cauliflower, beans, asparagus, tomatoes, eggs, cheese, butter, tea, coffee and cocoa. The indications for medicinal treatment are to curb and regulate the nervous apparatus which controls the glycogen function; to improve the blood and circulatory system, and to prevent the micro-organisms from interfering with the complete and perfect digestion of the food products. He believes that these indications are met in a combination of the double bromide of gold and arsenic which he has found most efficacious in many cases, given in doses of five minims, three times a day, after meals, and increasing the dose one minim each day thereafter until the physiological limit has been reached. This is shown by the evidences of arsenical poisoning, such as puffiness of eyes, a tendency to diarrhea, colicky pains and gastric disturbances. In some cases ten-drop doses will cause the above symptoms.

Leucocytosis.—Although the counting of leucocytes has become an almost routine method of aiding in differential diagnosis in regular hospital work, and also to determine in many cases the indications for operation, the ordinary physician still finds it usually too troublesome for private practice. Its value, however, should be thoroughly appreciated and the method employed more often than it is at present. J. H. Bursch (*N. Y. Med. Jour.*, March 31, 1900) reports several cases in which the determination of the leucocytes materially influenced the diagnosis. In one case, with typical symptoms of appendicitis, an absence of leucocytosis led to a thorough investigation which revealed a condition of impacted feces. In pneumonia, there is usually a leucocytosis of a polynuclear type. In severe cases the leucocytes are enlarged, the nuclei often fragmented and irregularly stained. When a change for the better occurs the cells become more distinct, the nuclei clear and deeply stained. In one severe case with a deficient leucocytosis, the polynuclear cells were of immense size, badly stained and with fragmented nuclei. Nearly all inflammatory and infectious diseases are characterized by leucocytosis, the principal exceptions being typhoid fever, measles, influenza, malaria and tuberculosis. Some observers believe that an early diagnosis of phthisis can be made out by the presence of a degenerative process within the leucocyte. The author has not been able to confirm this, but always finds the peculiar degenerative processes present in the later stages. In tuberculosis the large mononuclear lymphocyte seems to predominate.

Locomotor Ataxia.—A review of the pathology, symptoms, early diagnosis and treatment of tabes dorsalis appears in the *Med. Record* (March 31, 1900) by B. C. Loveland. The fibrous degeneration is supposed to begin peripherally either in the sensory nerves or the posterior spinal ganglia and travel along the affected nerve to the cord, and then passing upward to the cell into which the afferent impulse is discharged. Among the early diagnostic symptoms he mentions a feeling of great weakness, a tendency to stagger at night when going to bed, a feeling of numbness in the limbs, a velvety, or padded sensation in the bottoms of the feet, and sharp, shooting pains in the legs. An early sexual excitement may be noticed, followed by a partial or complete impotence. Crises sometimes occur soon after the onset, most often gastric, accompanied by intractable vomiting. The pupils may be unequal in size, may be Argyll-Robertson in type, or may be sharply and firmly contracted. Loss of knee-jerks is especially common and among the cerebral symptoms, insomnia, vertigo and depression may be mentioned. For the relief of pains the author uses phenacetin, gr. v., and caffeine citrate, gr. ss., given as occasion requires. In early cases it is almost always advisable to try for a short time a specific treatment, since from eighty to ninety per cent. of the cases are said to have had syphilis. Rest is very important, and yet proper exercise is also essential to teach the patient how to perform with care and precision, aided by sight, those motions which can no longer be done automatically. Massage and faradism give relief in some instances. Stretching of the spine by the Sayre apparatus has now been generally discarded on account of its dangers. The same result can be obtained by seating the patient on the floor with legs extended and then having him bend forward as far as possible, the physician adding graduated pressure on the head. This position is supposed to increase the size of the openings between the vertebræ through which the nerves and blood-vessels pass, thus increasing the circulation of the spine.

For Gingivitis.—

INOPERABLE SARCOMATA.

It is less than twenty years since one of our most distinguished American surgeons said that he did not think he had ever seen a case of cancer that had been cured even by the most radical surgical measures in use up to that time. Operative recovery took place, succeeded by a period of comparative ease of mind and physical comfort for the patient, but inevitable recurrence closed the scene.

Recent advances in surgery, many of which we are proud to say are due to American surgeons, have removed this opprobrium. Of the radical cure of cancer we may now speak with confidence. It remains true, nevertheless, that about three-fourths of all the malignant tumors, either from extension or metastasis, become eventually inoperable. So rapid is the growth of sarcomata, especially sarcomata of the internal organs, that not infrequently these tumors are seen by the surgeons only when they have gotten beyond the reach of aid by operative procedure. Nearly every great surgeon has, however, reported one or more cases in which infection of the tumor, either at an incomplete operation or from an exploratory incision, has been followed by complete and lasting disappearance of the neoplasm. The therapeutic secret thus, unfortunately, so obscurely hinted at is a most precious one and the endeavor to wrest it from Nature must certainly be alluring.

The use of mixed toxins of the bacillus erysipelatosus and the bacillus prodigiosus is the only attempt to follow in Nature's footsteps in this matter that has thus far met with any mead of success. Seeing the absolutely hopeless nature of the cases for which the "mixed toxins" treatment is suggested, it should be borne in mind that scarcely a month passes by in which some notable improvement or absolute cure by this method is not reported. In a recent review of the subject before the New York Academy of Medicine, Dr. Coley, the inventor of the "mixed toxins" treatment, reported that out of 140 cases treated by himself more than 50per cent. have been markedly improved, the rapid course of the malignant affection has been rendered slower for a time at least, and many symptoms have been relieved. In about 10 per cent. of the cases absolute cure has resulted. In the 230 cases reported by various observers nearly the same proportion of improvement and cures has obtained.

A radical surgical operation, wherever it is deemed possible, must still remain the ideal treatment of sarcomata, but for hopeless cases and even as an adjunct to surgical treatment the injections of the mixed toxins seems indicated. The mortality from the injections is practically nil. Two deaths have been reported in 230 cases and these, in hopeless sarcomata, with the well-known liability they involve of sudden serious complications, can scarcely be thought as due entirely to the injections. If twenty years ago a method of treating mammary cancer had been devised which brought about the radical cure of 10 per cent. of the cases, it would have been considered a most welcome addition to therapeutics. The use of the mixed toxins for sarcomata would seem to be at least as effective in its results as were the old partial operations for mammary cancer. Disappointing, then, as is the treatment in many patients, its possibilities must not be forgotten, especially in the hopeless cases. Further observations may yet win for us the secret of the powerful influence of the toxins on certain tumors and, perhaps, reveal a great therapeutic principle.

THE PATHOLOGICAL INSTITUTE.

At the time of writing, no change has been made in the attitude of the State Commissioners

toward the Institute. Their policy evidently has resolved itself into a determination to rule or ruin. In a previous editiorial we called attention to the fact that the Commissioners were assuming to themselves altogether too unwarranted a rôle when they presumed to pronounce upon the fate of this institution or even to control in too dogmatic pronunciamentos the range of its excursions into general science.

It has been and is an acknowledged fact that in psychiatry the various theories have been exploited, worked out and exhausted. The routine asylum work consisted in simply going around in a circle, with no particular point of departure and no definite termination. It was the conviction that some new line of enquiry must be blazed through the tangled mass of facts to lead out into brighter light, a freer air and a loftier point of view. The hope of such a consummation lay in a Pathologic Institute that should have the greatest latitude in its research, a free hand and a generous support. Reasonable time too was to be allowed it to work out its conclusions and substantiate its theories. What are the results? An immense amount of work has been done; some substantial conclusions have been reached—new in their conception and application, and many others are in process of incubation. But in exploiting a new field of enquiry all reasonable clues must be followed although the majority of them prove illusive. Much time is thereby consumed and the results are simply negative or too illusory to follow. It is to be feared however that the State Commission whose investigating committee had prejudged the situation has been too hasty in its condemnatory judgment. The verdict of the State Commission in Lunacy, of which Dr. Wise is the President, and of his committee of judges, of which Dr. E. Cowles of McLean Hospital is the Chairman, is hostile to the scientific psychiatric work carried on by the Institute. The verdict is: No scientific work in psychiatry; return to practical routine.

How long will it require for the so-called "experts" and men of "authority" who have such absolute control of psychiatry as to suppress anything that goes counter to their preconceived notions to realize that restricted traditional and routine lines are not the only lines of research in psychiatry having practical outcomes? Will the psychiatric profession permit with impunity a man to set himself up as the leading psychiatrist of the country and suppress an Institute the value of whose scientific work is acknowledged at home and abroad? Is it to be permitted that an Asylum Superintendent shall become a psychiatric pope and strangle all scientific life-activity that does not conform to his ideas and prejudices? Is psychiatric science to be relegated to the middle ages and throttled by inquisitorial committees? Shall American Psychiatry submit to the indignity of having a grand inquisitor at the McLean Asylum? These are some of the questions we ask the medical profession of New York State to consider before they supinely submit to the execution of the judgment already recorded by the State Commission in Lunacy.

MASTERS OF MEDICINE.

The fifth volume in the series of "Masters of Medicine," published by Longmans, Green & Co., has just appeared. The volume is devoted to the life and career of Herman Von Helmholtz and is written by John G. McKendrick. The previous volumes were devoted to John Hunter, William Harvey, Edward Jenner, and Sir James Simpson. The volumes are all of uniform size and binding and are most attractive in every particular. The books are not large, indeed, they can be carried conveniently in a large overcoat pocket, and so can be always at hand to enable the doctor, if he has been thoughtful enough to slip one of these volumes into his pocket, to fill in any odd moments that may fall to him in making his rounds. The medical man can find no greater inspiration for hard work and great achievements than in these admirable sketches of these masters in medicine. The salient characteristics of the various men discussed are presented in a clear and concise manner. Every doctor should have these volumes within convenient reach. The more frequently he consults them the loftier will be his aims and the greater his devotion to his chosen profession.

ECHOES AND NEWS.

NEW YORK.

A New Clinic Building.—Through the beneficence of a wealthy New York lady a clinic building, adjoined St. Bartholomew's parish house on East Forty-second Street, is about to be constructed. It will cost $150,000 and will have an endowment of $100,000. It will be devoted to dispensary and hospital purposes.

The Middleton Goldsmith Lecture.—Under the auspices of the New York Pathological Society, the Middleton Goldsmith Lecture will be deliv-

ered at the New York Academy of Medicine Friday evening, April 13th, at 8:30 o'clock, by Professor Simon Flexnor, Professor of Pathology in the University of Pennsylvania, subject: The Pathology and Etiology of Dysentery. The medical profession is cordially invited to attend.

Nurses Harmonize.—The nurses of the alumnæ associations of the Bellevue, New York, Post-Graduate, and Presbyterian Hospitals combined this year to have a course of lectures upon subjects of practical interest to their profession. One of the benefits of the lectures has been the increasing feeling of comradeship among nurses of different schools.

Dr. Chapin Medical Examiner.—The State Board of Regents has appointed Dr. Edward Chapin, of Brooklyn, a member of the State Board of Medical Examiners to fill the vacancy caused by the death of Dr. A. R. Wright, of Buffalo.

New Hospital for Women.—The Hospital Guild of the New York Medical College and Hospital for Women is rapidly accumulating a fund with which to erect a hospital building in connection with the medical college in West One Hundred and First Street. The land has recently been purchased and the building is expected to be ready for occupancy in the fall.

The State Sanatorium.—The bill providing for the establishment of a State hospital in the Adirondacks for the treatment of patients in the incipient stage of pulmonary tuberculosis has passed the Senate, but is meeting with opposition in the Assembly. A delegation of physicians headed by Dr. George W. Brush, of Brooklyn, called upon Senator Platt recently and urged him to use his influence to secure the passage of the bill. Senator Platt assured his visitors that he considered the bill a good one and would do all he could to secure its enactment.

Contagious Diseases.—For the week ending March 31, 1900: Measles, 853 cases and 31 deaths; diphtheria, 253 cases and 37 deaths; laryngeal diphtheria (croup), 16 cases and 8 deaths; scarlet fever, 159 cases and 16 deaths; smallpox, 1 case; chicken-pox, 27 cases; tuberculosis, 219 cases and 171 deaths; typhoid fever, 17 cases and 6 deaths: cerebrospinal meningitis, 9 deaths. Totals, 1545 cases and 278 deaths.

Christian Science Defined.—Mr. William A. Purrington, the counsel of the County Medical Society, in a lecture delivered on Sunday last, before the class for the discussion of present day problems at the Broadway Tabernacle, defined Christian Science as follows: "Christian Science is the presumptuous assertion that in 1866 God revealed to a chronic invalid—drifting from one physician, one school of medicine, one phase of quackery, to another, as the hysterical do—truth that during long centuries He has hidden from priests, scholars, poets, and even the simple, and gave to her a key to unlock the sealed book of the Scriptures, with the extraordinary result that, to use the discoverer's own words, 'Most of the knowledge I had gleaned from schoolbooks vanished like a dream.'"

Obituary.—Dr. John Cooper, said to have been the oldest practising physician in Brooklyn, died on Thursday at the Seney Hospital, where he had been treated for three weeks for gangrene of the foot. He was eighty-five years old, and was born in London, England. He was graduated from the Royal College of Surgeons in 1837, and for some time after that date traveled through the British possessions in South Africa as Surgeon to the British Army. He was a member of the New South Wales Medical Board for a number of years. He settled in Brooklyn in 1858, after having lived in Huntsville, Ala., for about twelve years. He was an honorary member of the Kings County Medical Society; Clinton Commandery, Knights Templar; Kismet Temple of the Mystic Shrine, and of the Brooklyn Masonic Veterans. He was also a thirty-third-degree Mason. He leaves a married daughter.

Medical Legislation.—The bill exempting the Bath Soldiers' and Sailors' Home from the supervision of the State Board of Charities has passed the Assembly. This does not prohibit inspection by the State Board of Health. The bill providing for the establishment by the City of New York of a hospital for the treatment of pulmonary tuberculosis, and appropriating $350,000 therefor, has passed the Assembly. The local board of health is to have jurisdiction over the new hospital. The Governor has signed the bill authorizing the transfer to New York City of the property of the Brooklyn Homeopathic Hospital. The conditions upon which the property is transferred are that it shall be maintained by the City as a homeopathic hospital. A bill has been introduced in the Assembly giving to the driver of an ambulance in New York City when on duty the right of way over all vehicles in the streets, except United States mail coaches. The bill providing that the Gerry Society should be subject to inspection by the State Board of Charities has been stricken from the calendar, and will probably not be heard of again.

Charities Conference Planned.—The State Board of Charities has undertaken to initiate a movement for the organization of a conference of charities and correction, designated to meet annually in this State, for the purpose of considering and discussing questions of importance in relation to the public and private charitable and correctional work of the State. The proposed conference will be made up of delegates from all the institutions of such nature. The present purpose is to form a provisional committee of fifty, as representative as possible, which shall undertake the organization of the conference and shall arrange a program for its first annual session, to be held, if possible, at Albany, October next. Dr. E. V. Stoddard is chairman of the committee

of the Board of Charities which has this matter in charge.

The Culture Test for Diphtheria at Ithaca.—Dr. Eadie, of Ithaca, N. Y., differed from the Health Board in regard to the quarantining of houses where suspected diphtheria patients were residing during the recent epidemic in that city, and would not respect the rules laid down by the Board. He objected to the quarantine which the Board put on the residence of one of his patients, for the reason that he considered his patient had recovered entirely from the disease. The Health Board ordered a culture to be made. Dr. Eadie made one and sent it to the Health Board, which found in it diphtheria bacilli and ordered the doctor to subject his patient to the quarantine. Then Dr. Eadie stated that he had made the culture from his own throat. Upon this the Board ordered Dr. Eadie to the contagious ward of the City Hospital. Dr. Eadie went to the Hospital, and while there consulted counsel, who advised him to leave the Hospital without considering the Board of Health. This he did and, moreover, declared that he was exposed to contagious diseases while in the ward and that if he should become afflicted with any of them it would go hard with the men who were responsible for his confinement there. Up to March 29th the Health Board has taken no action.

PHILADELPHIA.

Health Report.—The death-rate in this city is abnormally high at present. The number of deaths for the week ending March 31st was 679, an increase of 42 over those of last week and of 175 over the corresponding week of last year: Contagious diseases: Diphtheria, 81 cases, 15 deaths; scarlet fever, 23 cases, 4 deaths; typhoid fever, 79 cases, 13 deaths. There were 29 deaths from influenza.

Almshouse Officials Censured.—The Coroner's jury which held an inquest upon the body of an inmate of the Philadelphia Hospital has censured the officials for detailing inmates suffering from nervous diseases to attend patients. The man in question died of heart-disease, his death being hastened by a broken arm alleged to have been caused by the roughness of his attendant who was one of the patients. The Coroner also severely arraigned the management for this practice.

Gouty Uterus and Appendages.—At the German Hospital March 31st Dr. John B. Deaver found an interesting condition in the pelvic organs of a woman operated upon. The case had been diagnosticated uterine fibroid before it was sent to the hospital; but from pelvic examination and the fact that certain fingers of one hand were flexed and contained calcareous deposit in the contractures, a diagnosis of a similar deposit in the pelvis was made. Operation verified this. Portions of the uterus, tubes, and the ovaries were the seat of calcareous deposit, this filling the pelvis with a nodular, irregular mass. The entire mass was removed by a supravaginal hysterectomy. The patient was fifty-two years of age.

Academy of Surgery.—At the meeting of April 2d, Dr. F. J. Stewart reported a case of green-stick fracture of the fifth rib in a boy six years of age. Pneumothorax followed, the apex beat of the heart being at the right nipple line. The pleural cavity was aspirated several times, but the condition was not cured until drainage was made. The boy was discharged the seventy-sixth day, came back nine days later with pneumonia of the right base, and died five days after.

Dr. Orville Horwitz described a case of urethrorectal fistula due to an acute posterior urethritis. The fistula was finally cured after three operations, one of these being a preliminary suprapubic cystotomy.

Dr. R. G. Le Conte exhibited a specimen of intraligamentary fibroid with beginning carcinoma of the fundus of the uterus. The patient was a single woman thirty-six years of age. The tumor extended two inches above the umbilicus, the growth projecting from the left side of the uterus and being covered by the folds of the broad ligament. The uterus was amputated at the level of the internal os. After removal a carcinomatous degeneration of the fundus of the uterus was found. This extended to within three-fourths of an inch of the level of amputation. The question of removing the stump then arose. Dr. C. B. Penrose stated that he had removed the uterus in three cases for some other reason and had found carcinomata extending to very nearly the point of amputation. The last case was operated on four years ago and in none of them had there been a recurrence. Hence, operation has not been suggested in this case.

County Medical Society.—The meeting of March 28th was devoted to a consideration of the menopause. Dr. John G. Clark gave a lantern demonstration of "The Anatomical Basis." This is founded on the arrangement of the vessels in the center of the ovary. They are numerous and of a corkscrew shape, and when congested cause the pushing out to the periphery and rupture of the Graafian follicles, this congestion beginning several days before menstruation. After a time the blood supply from this central tree is not sufficient to nourish the follicles as the central area becomes filled in with scar-tissue. This forms the anatomical basis, as follicles are still found at the periphery after the menopause but do not get nourishment enough to develop and rupture. The menopause is thus not the result of a physical condition, as women are in the prime of life at that time, but is due to the local condition in the ovary.

Dr. J. B. Chapin spoke of the "Psychoses of the Menopause." He stated that these psychoses are not an entity, the women who have them at that time being those of a highly neurotic tendency or those who have suffered from attacks of in-

sanity during their menstrual life. Of the patients admitted to the insane department of the Pennsylvania Hospital during the age of puberty, between the fifteenth and twentieth years, there were 284 men and 276 women. At the period of the menopause, or between the forty-fifth and fifty-fifth years, there were 975 men and 876 women. It is thus seen that at the age of both of the important sexual periods of the female more males than females are afflicted with insanity.

Dr. J. M. Andrews discussed the "Cardiac Manifestations." In the majority of the instances of marked cardiac involvement a neuropathic tendency is the underlying and predisposing cause. He has observed two cases of tachycardia, one after the natural menopause, the other after operation. In both cases the pulse reached 200 per minute for an hour or two at a time. The intervals between the attacks were two to three months in one case. One case of bradycardia was observed. Arythmia is the disturbance found in obese subjects. All forms are aggravated by a premature menopause.

CHICAGO.

St. Anthony's Hospital, Rock Island.—A Training School for Nurses has been established in connection with this institution.

Chicago Woman's Club.—This Club has started a movement to establish a hospital, and in its course of instruction women will be trained for the work of the Red Cross Society.

Will of Dr. Edward L. Holmes.—The will of Dr. Holmes was admitted to probate March 26th. The estate is valued at $55,000, of which $50,000 is personal property.

Food Adulteration.—Professor C. L. Kennicott said that during his term as chemist to the Chicago Health Department, he had examined almost every variety of food, with the result that he was convinced that nearly all manufactured products sold for consumption by man and beast are adulterated. The evils of this practice fall most heavily on the poor.

Child-Study Committee of the Board of Education.—The Child-Study Committee of the Board of Education has asked permission to assume charge of the testing of the eyesight of schoolchildren and to establish a laboratory in the rooms of the Board for the examination of backward pupils. The system of sight-tests which was put in by the Board two years ago was without superintendence, and it was discontinued for the present year. The laboratory for the examination of children found to be backward will be under the supervision of Professor F. W. Smedley, Director of Scientific Pedagogy and Child-Study. As there has been no provision made for the specific treatment of children below normal, the laboratory is planned for the special examination of these with the idea of finding means of correction. The special examinations will include tests of eyesight and hearing.

Board of Education Sustained.—The right to exclude from the public schools any pupil who has been ill, until passed upon by the regular medical inspector of the Board of Education, was sustained in a decision handed down by Judge Ball in the Superior Court a few days ago. The opinion was given after the hearing of a petition for a writ of mandamus against the School Board to allow a pupil to return to her classes without first having passed a medical examination.

Mortality Statistics.—There were 640 deaths during the past week, the greatest number ever recorded during any week in the history of Chicago. This greatly increased mortality is due to influenza. Although only 4 deaths from this affection are recorded, it is reported as a fatal complication in the majority of the 159 deaths from pneumonia, the 72 from consumption, the 54 from heart disease, and the 154 of persons over sixty years of age. The medical inspectors and members of the disinfecting staff of the Department report great laxity in the preventive care of influenza patients. The infectious character of the disease does not seem to be generally recognized.

Smallpox.—The recent smallpox developments also, according to Health Commissioner Reynolds, demand attention. Last year there were 23 cases of the disease in Chicago, of which number 11 were imported; the remaining 12 were contracted from the imported cases. Thus far this year there have been 9 cases—6 imported and 3 developed among residents of the city without known exposure to the importations. The presumption is that the contagion is as widely spread here as it is known to be throughout the country generally, but that the disease is so mild as to escape detection in many instances.

Changes in Rush Medical College.—It is said that Dr. Arthur R. Cushny, of the University of Michigan, has been tendered the Department of Pharmacology and Materia Medica in this college. Judge Henry V. Freeman will lecture on Medical Jurisprudence. Dr. E. P. Bradley, of the Polytechnic Institute of Peoria, will be Assistant Professor in Physiology. It is intended to erect a new building upon the lot adjoining Rush College, and it is highly probable that the structure will be modeled after the one at Johns Hopkins University. It was expected that the building would be completed so that work could be begun in it this fall, but owing to unsettled conditions this has been deemed impossible. The principal use to which the new structure will be put will be that of higher clinical work and lectures.

The Facts Regarding Criminal Abortion.—Dr. Denslow Lewis estimates that 80 per cent. of all married women who become pregnant wish they were not. Old ladies recommend the use of different teas, hot douches, hot baths and violent exercise. Cathartics, emmenagogues, and ergot are advised, and, among the ignorant, arsenic, metallic mercury or other poison has been taken, usually with fatal result. These means often fail.

Cases are cited where women fell from great heights, sustained fractures, were beaten to unconsciousness, and suffered even fatal traumatism without severing connection between mother and child. At other times very slight injury produces abortion. Alum water injections have caused death. One woman produced abortion upon herself thirty-five times with a knitting-needle. Death has occurred simply from the introduction within the uterus of a cannula. The intra-uterine injection of glycerin has proved fatal. An embolism has occurred, also mercurial poisoning, from a bichloride douche. The uterus is not always entered by the foreign body. Thomas's case is cited in which a physician's wife passed an umbrella rib through the vaginal vault, the abdominal cavity and diaphragm until it perforated the lung. Other cases are instanced where an elastic sound encircled the cervix for two and one-half years and where metastatic abscesses formed in brain and elsewhere. Lewis cites a case of his own in which a silver catheter had perforated the posterior uterine wall and was removed from under the liver by abdominal section. In this case the pregnancy was uninterrupted. Other cases show a glass rod retained in the broad ligament, a seatangle tent found posterior to the uterus, a needle 7 cm. long, observed in omentum during the performance of Cæsarean section. Sometimes no discomfort results, at other times a suppurative process causes its expulsion into adjoining viscera. A fatal injury of the internal iliac artery is recorded. Utero-intestinal fistula has occurred. Two cases are instanced where a knitting-needle was forced through the umbilicus into the uterus. The relation of repeated abortion to degenerative changes and diseased states of the nervous system is considered as well as the production of sterility by infection of the tubes.

The Pathology of Criminal Abortion.—Dr. Maximilian Herzog read a paper on this subject. He said that the pathology of criminal abortion has to establish, first, the causal nexus of premature expulsion of the ovum by the aid of internal medicinal or external mechanical means adopted for the accomplishment of the desired criminal attempt; second, to account for the illness or death of the mother during or after the abortion. By far the largest number of criminal abortions are brought about by internal medicinal agencies which enjoy the reputation of being reliable abortifacients. According to Lewin, certain medical preparations have the property to primarily or secondarily exert a pathological influence over the uterus and the ovum contained in it. We possess certain poisons which can influence the uterus in such a manner that phenomena similar to those in parturition are produced, and that the ovum becomes detached from the fruit-bearer. But all internal means which, if taken in sufficiently large doses, may bring about this cycle of changes are substances poisonous to mother and child alike. They have the property to bring about morbid disturbances of physiologic functions. The hemorrhages caused by internal abortifacients occur between the fetal membranes into the amniotic cavity or into the placenta; they lead to a loosening or separation of the ovum. Other pathologic processes noticed in connection with the internal use of abortifacients are hyperemias in distant organs of the mother, inflammatory processes in the gastro-intestinal tract, the pelvic organs, and in the ovum and its envelopes. Some abortifacients primarily and particularly act upon the gastro-intestinal tract and exert their influence secondarily only on the pelvic organs. From the studies which he has made on the normal and abnormal uterine placenta and the placenta in tubal pregnancy, he is inclined to believe that the first step in bringing about spontaneous abortion is very frequently a hemorrhage into the intervillous space, and hemorrhages into the spongy layer of the decidua serotina. These hemorrhages come from the uteroplacental sinuses, and their effect must be a loosening, eventually a separation of the ovum. The author outlined the general principles of the pathology of criminal abortion and characterized them as follows: (1) Premature expulsion of the ovum, if it occurs as the result of the internal administration of abortifacients, is an integral part of the general toxic symptoms, changes and processes due to those drugs or chemicals acting deleteriously upon both mother and child. (2) Premature expulsion of the ovum, if it occurs after detachment of the membranes, perforation of the amniotic cavity, etc., is brought about because after such manipulations which may or may not bring about the speedy death of the embryo, the ovum acts as a foreign body and stimulates the uterine muscularis to contractions, or because intervillous or interdecidual hemorrhages occur. (3) Septic infection in its broadest sense following criminal abortion is, *ceteris paribus*, not fundamentally different in its general and special pathology, its sequelæ and complications from other septic infections.

GENERAL.

The Medical Association of Missouri.—The forty-third annual meeting of this association will be held at Mexico, Mo., May 15th, 16th, and 17th. A symposium on gall-stones will be a feature of the meeting. Arrangements have been made for an exhibit of pathologic specimens.

In Memory of Dr. Love.—On March 31st the Love Memorial Association presented to the Free Library Association of Montclair, New Jersey, a bronze bust of the late Dr. John J. H. Love, made by J. Scott Hartley, the sculptor. Many persons witnessed the presentation and appropriate ceremonies were held.

Dr. Dewey Not Insane.—Dr. Richard Dewey writes that the report of his insanity was a mistake, or an intended joke, or, possibly, a piece of malicious mischief. We regret that this report should have appeared in our columns, although the circumstances were such as to give it cre-

dence, and gladly announce that Dr. Dewey is in his usual good health.

Quarantine against Cuba.—On April 1st the United States Gulf and South Atlantic ports began their quarantine against Havana. The approach of that date warned visitors in Havana and the fear of quarantine started them for home; every stateroom and every available cot on all the steamers leaving Havana March 31st were occupied.

Lombroso on the Bicycle.—Professor Lombroso, who seems desirous of bringing the science of criminology into disrepute, counts on a dreadful increase in crime when the passion for the bicycle reaches Southern Italy. In an article on "Bicycling in Crime" in the *Nuova Antologia* he states: "Of all the mechanical inventions of our time, none has obtained such extraordinary importance as the cause or instrument of crime as has the bicycle. If the somewhat exaggerated opinion was formerly held, that the cause of every male crime should be sought in woman, as is expressed to-day by the too celebrated phrase, '*Cherchez la femme!*' with perhaps less exaggeration, one might say, 'Seek the bicycle!' The motive for a great part of the thefts and robberies committed by young members of good society, in Italy at least, is found in the desire to possess a bicycle."

Dishonest Doctor Convicted.—Dr. Adolph Zeil, of Berlin, was found guilty on April 2d of the charge of having made money by incapacitating young men for military service. His plan was to administer on the day before the examination such drugs as would accelerate the heart's action. The prospective recruit would be rejected on the ground that he was suffering from heart-disease. Zeil had "treated" 350 in this way. He was sentenced to one year's imprisonment and the various civilians and military surgeons who were implicated were each sentenced to a few months' imprisonment.

Care of New Jersey's Insane.—Arrangements were completed on March 29th at the Trenton State Hospital for the transfer of between sixty and seventy-five lunatics from the State institution to the city of Bridgeton. Under the law, the county to which any inmate of the State Hospital is chargeable must pay to the management of the State Hospital $3.00 per week for each such inmate. The State also contributes $2.00 per week per inmate toward the support of the State Hospital. Several years ago a law was enacted empowering any county to build a county asylum and care for its insane. To support the county institution the State is to pay the $2.00 per inmate that heretofore has gone to the State institution. It was upon this understanding that the county asylum at Bridgeton was built.

The United States Army Ration.—Captain E. L. Munson, Assistant Surgeon U. S. A., in his essay upon the ideal ration for an army in the tropics, which was awarded the Louis Seaman prize for the best essay upon that subject, outlines the ration as follows:

	Quantity per ration (ounce).
Fresh beef (quarters)	10.00
Fresh mutton	10.00
Pork	6.00
Bacon	6.00
Salt Beef	10.00
Dried fish (cod)	10.00
Fresh fish, average (whole)	14.00
Flour	18.00
Soft bread	20.00
Hard bread	18.00
Cornmeal	20.00
Beans	2.40
Peas	2.40
Rice	4.00
Hominy	4.00
Potatoes	16.00
Potatoes, 80 per cent. and onions 20 per cent.	16.00
Potatoes 70 per cent. and canned tomatoes 30 per cent.	16.00
Dried fruit (average)	3.00
Sugar	3.50
Molasses	1 gill
Cane syrup	1 gill

The Hospital Ship "Maine."—The Executive Committee of the American hospital ship "Maine" has received the following letter from the Lord Mayor of London, A. J. Newton: "I inclose you a check for £2000 from the Transvaal War Fund to be applied to the beneficent work the American hospital ship 'Maine' is doing for sick and wounded troops. The check represents some of the contributions Americans have made to the fund, and it therefore does not infringe on the graceful determination of your committee to accept only American money for the humanitarian purposes of the 'Maine.'" Sir William MacCormac, who recently returned from South Africa, says everything that could be desired for the comfort of the wounded, both from a surgical and nursing standpoint, is to be found on the "Maine." Practically there is nothing which "Tommy Atkins" asks for which he is unable to get.

Attack on Dr. Backus.—In the Senate at Albany on April 3d Senator Raines reopened the case of the removal of Dr. Truman J. Backus from the board of managers of the Long Island State Hospital. In the course of a vicious attack he charged that Dr. Backus, first, obstructed the making of reforms in the institution; second, that he placed in control of the institution unfit persons; third, that he charged large amounts of personal expenses to the State; fourth, that he let contracts to personal friends without opening bids; fifth, that he used the stores for personal use; sixth, that he sold property of his own to the State hospital of which he was a manager, this he said being a criminal proceeding.

In answer to Senator Raines' attack, Dr. Backus stated that there ought to be a thorough investigation made by the proper authorities of each of Senator Raines' charges and that he should welcome such an examination.

A Kentucky Physician Buncoed.—A physician of Trisler, Ky., on Saturday morning, on Broad-

way, met two or three men, and one of them led him to believe that he had known him in Kentucky. The doctor went with them to a place near Park Row and the Bowery, and in a spirit of friendship cashed a check for $400 for the one who claimed to have known him in Kentucky. The check turned out to be worthless. The physician was in New York preparatory to taking a trip to Europe, but after the loss of his money he returned to his home in Kentucky.

Mrs. Eddy's Illness.—The New York *Evening Post* of April 3d states that Mrs. Mary Baker G. Eddy, leader and founder of the Christian Science Church, is very ill at her home in Concord, N. H., with a cancerous affection.

Obituary.—Dr. Charles J. Hall, a life-long resident of Glen Cove, and a widely known physician in that section of Long Island, died on March 29th.—Dr. William W. Rodman, one of the oldest practising physicians in Connecticut died in New Haven on March 30th, in his eighty-third year.—Dr. Joseph H. Vondy died in Jersey City on April 2d. He was born in New Brunswick, Canada, in 1829. He was graduated from the New York University Medical College and began practice in Jersey City in 1851. He was one of the founders of the City Hospital.—Dr. J. Sterling Bird, of Hyde Park, New York, a prominent Dutchess County physician, died on April 3d, in his sixty-fourth year. He began practice in Hyde Park in 1865. He was an influential member of the Dutchess County Medical Society.

The Plague.—The San Francisco Board of Health announced March 24th that several more cases of bubonic plague had been discovered in Chinatown. All Chinese leaving the city by boat or train are compelled to show certificates of a clean bill of health. In the meantime, the house-to-house inspection of Chinatown continues, and the systematic cleaning of all insanitary houses and yards is being prosecuted. The plague is steadily increasing in Calcutta and Bombay. It is rendered more fatal by the famine. The famine expenditure for 1899-1900 was over $10,000,000. It is estimated that the expenditure for 1900-1 will be over $15,000,000. A strenuous effort is being made to destroy the rats both at Hong Kong and in Japan. A premium is offered on dead rats in the latter country, and in the former place rat-traps are being widely distributed. Since the beginning of the outbreak of plague at Sydney, Australia, fifteen persons have been attacked, of whom six died, one recovered and eight are still suffering from the disease. Eleven fresh cases of bubonic plague were officially reported April 1. Two additional deaths have occurred.

Medical War News.—It is reported from Pretoria that when British prisoners arrive careful lists are made of name, rank and condition. The military prison-camp is called the Waterfall and is occupied by 2600 British soldiers. The hospital arrangements are described as excellent, and fountain water is daily sent in tanks from Pretoria. The officers who have been captured are confined in the State Model School, which is modern and well built, has many large and lofty rooms, and is surrounded by a broad veranda. On the other hand, the treatment of the colonials of Natal and Cape Colony is hard; they are confined in the ordinary jail and are treated like common criminals. The total list of casualties in the British army up to a recent date is estimated at 15,849, of whom 2041 have been killed and 9356 wounded; 930 have died from disease. Sir William MacCormac, in describing (*Lancet*, March 17) the scene at the field-hospital after the battle of Spion Kop, says:

"About seven o'clock, just on the approaching sudden darkness of the tropics, a barely distinguishable moving mass of men could be seen coming over a distant hillock. This was the leading stretcher of the convoy and it had reached us before the end of the train of stretchers and wagons came into view. Hot bovril and stimulants had already been prepared by the men of the Royal Army Medical Corps, great pots of the former resting in the kitchen. The hospital is surrounded by barbed wire fencing to prevent confusion and the entrance of unauthorized persons. There is an opening at one side at which Major Daly immediately stationed himself, accompanied by his staff sergeant. Each stretcher was lowered at this entrance, the nature of the wound was inquired into, and the patient, after identification, was conveyed by the men of the Royal Army Medical Corps to the vacant beds, a list of which was kept by the staff sergeant (each tent being numbered). Confusion was thereby greatly diminished and none of the native stretcher bearers were allowed to enter the enclosure; 43 stretchers and 12 wagon loads (100 cases) completed this convoy and most of the cases were serious. I was informed that there were still another 150 to arrive on the morrow. This terribly long line of brave fellows lying helpless, arriving one by one in the dusky light, coming over the horizon, accompanied by the moving shadows of the bearers, silently advancing in their bare feet, or singing a peculiar chant of their own as they wearily sped beneath the weight upon their shoulders, presented one of the most impressive and saddest sights imaginable, and every few moments the sad scene was lighted up by bright lightning flashes, making it still more pitiable. For 14 hours, with the exception of a short halt at midday, had this weary body of sufferers, sick with their wounds and sad at heart with their defeat, wended its way across the hot and dusty veldt. The day happened to be a terribly hot one. At night the lanterns of the hospital attendants flitted hither and thither among the tents. Wounds had to be rebandaged, splints readjusted, morphine injected, and in some cases operations to be performed at once. The orderlies moved about as rapidly as possible from tent to tent, the similarity of the tents in the darkness causing confusion in any one unfa-

miliar with the exact location of the different patients."

American Surgical Association.—The following is the provisional program of the meeting of 1900, at Washington, D. C., May 1, 2, and 3, 1900:

1. President's Address, Perforating Ulcer of the Duodenum, R. F. Weir, New York.

2. Gastric Ulcer Non-perforating—Hemorrhage, Wm. L. Rodman, Philadelphia.

3. Perforating Ulcer of the Stomach, J. M. T. Finney, Baltimore.

4. Benign Obstruction of Pylorus, Frederick Kammerer, New York.

5. Malignant Disease of Stomach and Pylorus, Wm. J. Mayo, Rochester, Minn.

6. Gastric Dilatation—Gastroptosis, B. F. Curtis, New York.

Hourglass Contraction of the Stomach, F. S. Watson, Boston.

8. Diagnosis of Cancer of Stomach, John C. Hemmeter, Baltimore.

9. Traumatism of Stomach, including Foreign Bodies, Rudolph Matas, New Orleans.

The discussion of Surgery of the Stomach will be opened by W. W. Keen, Philadelphia (ten minutes), and M. A. Richardson, Boston (ten minutes).

10. Stricture of the Esophagus following Typhoid Fever. Gastrostomy, Frederic S. Dennis, New York.

11. A Series of Demonstrations upon the Cadaver, illustrative of the Mechanism of the Various Dislocations of the Hip (by request), Oscar H. Allis, Philadelphia.

12. The Methods of Closing Abdominal Incisions, M. H. Richardson, Boston.

Discussion opened by John B. Deaver, Philadelphia.

13. Strangulated Hernia through a Traumatic Rupture of the Diaphragm—Laparotomy—Recovery, E. W. Walker, Cincinnati.

Discussion opened by N. P. Dandridge, Cincinnati, and S. J. Mixter, Boston.

14. A Case of Subpubic Hernia of the Bladder through the Pelvic Floor—Operation, P. B. Harrington, Boston.

Syllabus: Varieties of Hernia of the Bladder.—Causes.—Hernia of the bladder through the pelvic floor rare.—Hernia in the case reported due to traction of an edematous fibroid originating in the subperitoneal tissues in front of the bladder.—Treatment.

Discussion opened by J. Collins Warren, Boston.

15. A Case of Acute Tuberculosis of the Mesenteric Glands of the Ileocecal Coil—Removal—Permanent Recovery, M. H. Richardson, Boston.

16. Successful Removal of Acutely Inflamed Tubercular Mesenteric Glands, J. W. Elliot, Boston.

Discussion of Nos. 15 and 16 by Robert Abbe, New York, and S. Chalmers Da Costa, Philadelphia.

17. Congenital Cystic Tumor of the Pelvis, De Forest Willard, Philadelphia.

18. Extirpation of a Very Large Aneurism of the Renal Artery, W. W. Keen, Philadelphia.

Discussion opened by Wm. J. Mayo, Rochester, Minn.

19. Carcinoma of the Rectum, John B. Deaver, Philadelphia.

Discussion opened by C. B. Nancrede, Ann Arbor, Mich.

20. Spontaneous Disappearance of Carcinoma of the Lip. Union following Pathological Fracture of the Femur due to Secondary Carcinoma, Leonard Freeman, Denver.

Discussion opened by P. S. Conner, Cincinnati.

Association of American Physicians.—The following is the preliminary program of the meeting at Washington, D. C., May 1, 2, and 3, 1900:

1. The President's Address, E. G. Janeway, New York.

2. Discussion. Endocarditis, and Its Relation to Other Diseases. Referee: Wm. Osler, Baltimore.

3. Report of Cases of Pernicious Anemia, with a Special Reference to the Blood Findings, Frank Billings, Chicago.

4. Some Conclusions arrived at after a Study of 104 Cases of Pernicious Anemia, Richard C. Cabot, Boston.

5. Clinical Notes on Cases of Pernicious Anemia, Frederick P. Henry, Philadelphia.

6. Case of Filaria, with Specimens of the Adult Parasite, W. T. Councilman, Boston.

7. Cases of Diarrhea Associated with the Presence of Strongylus Intestinalis in the Stools, W. S. Thayer, Baltimore.

8. Actinomycosis, J. H. Wright, Boston.

9. Proliferation and Phagocytosis, F. B. Mallory, Boston.

10. The Relative Infrequency of Acute Transmissible Diseases during the First Year of Childhood, with a Discussion of the Probable Reasons for the Same, A. C. Abbot, Philadelphia.

11. Recurrent Vomiting in Children, J. P. C. Griffith, Philadelphia.

12. Would It Not Be a Gain to Both Pathology and Practice if a Direct Interaction between the Morbific Agent (Noxa) and the Reparative Effort Were Recognized, and the Conception of an Intermediate, So-Called Inflammatory Process Abandoned? Andrew H. Smith, New York.

13. Completion of Paper. (By Abstract.) Clinical Types of Uric Acid Diathesis. Treatment, J. N. Danforth, Chicago.

14. Communication on the Relation of Uric Acid Secretion to Epileptic Attacks. James J. Putnam, with F. Pfaff, Boston.

15. An Experimental and Clinical Study of Acid Intoxications, C. A. Herter, New York.

16. Report of a Case of Acute Ascending Paralysis, Showing Hematoporphyrinuria, Chas. G. Stockton, Buffalo.

17. Notes on Diabetes. 1. On Casts in the Urine During Diabetic Coma. 2. On the Occa-

sional Low Specific Gravity of Diabetic Saccharine Urine, James B. Herrick, Chicago.

18. The Attitude of the Physician and Surgeon to Appendicular Symptoms Complicating Typhoid Fever, H. A. Hare, Philadelphia.

19. Observation on Appendicitis, Ira Van Gieson, New York.

20. Subpectoral Abscess, J. H. Musser, Philadelphia.

21. Aneurism of the Aorta with Rupture into the Superior Vena Cava, Recognized During Life, Alfred Stengel, Philadelphia.

22. The Circular Fibers of the Heart (Mitral Sphincter) as a Factor in Functional Disturbances of the Heart with Mitral Insufficiency, Morton Prince, Boston.

23. Minor Forms of Cardiac Dilation, Beverly Robinson, New York.

24. Presentation of a Case of Addison's Disease under Treatment with Suprarenal Extract, W. W. Johnston, Washington.

25. Graves' Disease without Exophthalmic Goiter, W. H. Thomson, New York.

26. Some Observations on Human Temperature in Disease, Norman Bridge, Los Angeles.

27. Sanitarium Treatment of Pulmonary Tuberculosis, and Its Results, E. L. Trudeau, Saranac Lake.

28. The Elimination of Deleterious Substances from Antitoxic Sera, William H. Park, New York.

Papers will also be read by Drs. W. H. Welch, F. P. Kinnicutt, I. Adler, G. B. Ward, C. F. Withington, and J. S. Thacher, the titles of which will be announced in the final program.

CORRESPONDENCE.

HOSPITAL DAYS IN MANILA.

To the Editor of the Medical News:

Dear Sir:—We were fortunate on entering Manila to be able to take possession of the Spanish hospital, the Spaniards having removed their sick and wounded into the walled city. Although filthy and dismantled they were easily made serviceable. The principal wards were arranged around a large court rich in tropical foliage and provided with a band-stand to indicate that hospital life had its lighter moments. The wards were capable of accommodating each from seventy to one hundred men. The space for the most part was unbroken, allowing fine ventilation, and each was surrounded by a high-pillared roof over the outlying pavement, which at all times kept the temperature tolerable. Air chambers beneath the wards assisted in keeping the floors properly wholesome, although germs of malaria were suspected beneath. The baths were soon reconstructed, but the absence of sewerage put all toilet arrangements on a temporary basis. The other offices, surgery, pharmacy, kitchen, stables, morgue, were put into temporary use, but the work of remodeling to get them more into line with our needs immediately began.

Manila had an electric light plant; this was immediately introduced into the hospital. Big kettles under which the fires were always roaring provided boiled water for drinking, but soon yielded to the distilling apparatus which not only supplied the hospital, but provided distilled water for the troops at the front. An ice-plant on the grounds in time succeeded that at Cavite, on which we had at first to depend.

The sick by no means waited for these improvements. The weeks of mud and rain in the trenches of the Spanish campaign were more deadly than the Spanish bullets. The troops fairly fell over one another with dysentery, rheumatism, and typhoid fever. An outbreak of smallpox soon followed, which obliged the setting up of a smallpox-camp conveniently isolated on one of the vacant spaces which are a feature of the topography of Manila. The volunteers at that time still regarded campaigning in Luzon as something of a lark, and to their incursions among the native fruits and native vino is to be attributed a certain amount of the sickness which now befell the army.

The hospital accommodation soon overflowed. The California Red Cross Hospital was started and a Convalescent Hospital, now known as the 2nd Reserve Hospital, was established in one of the Exposition buildings in Ermita, as the district is known. All these hospitals, including the 3rd Reserve Hospital occupying the Wyoming barracks, are in easy reach of one another between the Pasig and Manila Bay where the fresh sea breezes have not lost their force.

Typhoid fever seemed to respond to treatment more easily than dysentery. I think it is generally admitted by the doctors that chronic dysentery cannot be cured in this climate, and such men I know were detailed to be sent home when a choice of patients was necessary. A German nurse at one time seemed to effect some marvellous cures among men who had lingered for months in bed. But it was found that the men relapsed as soon as they were out from under his treatment.

Typhoid fever gave much better results. My own experience at that time was in a fever ward, and during four months we lost but one man, an interesting case of purpura hemorrhagica. He was a Washington soldier, in the beginning a smallpox suspect. These were not infrequent; I have known in three days three smallpox cases to be removed, after having spent several days in the ward. The typhoid patients received ice-water treatment. It was a standing rule in the ward when a patient's temperature registered 102° to give him a bath. It is my pleasure to testify to the faithfulness of the hospital corps men in this ward in this respect. There was plenty of dirt, noise, and skylarking, but the moment the unfortunate reached the danger line he was either laid on a stretcher, covered with a sheet, and doused with ice-water, or he was put in a

crazy old bath-tub on little wooden wheels, and in his ice-bath rubbed down with blocks of ice until his temperature was lowered. This was done in primitive, vigorous fashion, frequently amid much joking, but the men recovered and so quickly that it was a pleasure to mark their progress from day to day. I was afterward in the Military Hospital in Calcutta, where enteric fever, as it is there called, is one of the scourges. "We depend on phenacetine," the doctor in charge said. "Ice is too expensive, and we have no ice-plant." It was pardonable to feel a little pride in our hospital ice-plant, turning out two hundred pounds an hour as half rations and prettily housed in a little vine-covered cottage.

We had two kitchens, one for the heavy diet and one for the light diet; the former alternately presided over by Chinese and Filipinos. The commissary occasionally broke down in one particular or another, but was generally abundant. Before the breaking out of hostilities, oysters, fish, caribou-milk and eggs were easily obtained from the natives. After February 4, 1899, it took a long time to obtain these articles of food for the sick. The effort to make condensed milk palatable and acceptable, so that the typhoid patients would take it, is among the great efforts of my life. Afterward we had evaporated cream in abundance. A dairy of Australian cows later helped us out. Two ships kept the troops provided with Australian beef and mutton. This we had at least four days in the week, and it spoiled the "heavy diets" for what they termed "red-horse," or alleged canned roast beef. Embalmed beef we were spared. The fresh meat was usually served as stews. I never was able to understand why the sick should not occasionally alternate with the stewards in getting roasts and chops. The lay mind naturally felt that nothing was too good for the soldiers if it was on hand. But let me say here the medical authorities granted all we desired when appealed to. The resistance came from the small gods who ruled over fires, pantries and stores, and one could not always be making complaints.

The events of February 4th and 5th made new demands on the hospital. The tension had been great for weeks, but the precipitation was at last a surprise. During Sunday, February 5th, the wounded were brought in on every conceivable conveyance, the ambulances performed but a tithe of the task. The procession of litters choked the passages; the wounded lay over the floor and corridor of the surgery, the sheltered pavements and the grass-plot. All that day the surgeons and their attendants stood at the operating-tables, and at midnight were still at work on the insurgents, whose wounds were much more terrible than those of our men, inasmuch as the Mauser is a polite missile compared with our Springfield, which tore the unfortunates to pieces. We had very few amputations and those were forlorn hopes. The surgeons feared the effect of the climate on the gunshot wounds. On the contrary I heard one of them say, "Flesh grows with the rapidity of all tropical growths." One of the first patients in the officers' ward, to which I was then attached, was Lieut. Hogan of the 1st Californias. He was shot through the body between the heart and lungs. He suffered comparatively little discomfort from his neat little drilled hole. Lieutenant-Colonel Wallace of the 1st Montanas was shot through the lungs, and was out in two weeks. The men who were so unfortunate as to be shot with Remington rifles were much more seriously injured. And occasionally a brass-tipped Remington gave a man a sharp struggle for his life. The penetrating power of the Mauser at long range was regarded as astonishing. Lieutenant Irwin of the Washingtons was stooping over an ammunition chest when a Mauser struck him in the back of the neck, came out, went in again and came out, making four holes. Another officer had six holes from one bullet. A third was shot through the forearm, the bullet then penetrating his leg was buried in the bone.

On the taking of Santa Tomas, a Kansas soldier was brought into the dressing station at Calumpit shot through the temples, the brains protruding two inches on each side. The surgeon wiped them off with a bit of cotton and dressed the wound. I took care of the man until the next day when he was sent to Manila. He remained unconscious for some time and Captain Straub, the doctor in charge of his ward, doubted his recovery, or if he recovered that he would again have the power of speech. Subsequently I saw him on the "Relief," looking well, cheerful, talking, but ignorant until I told him of where he was wounded and of any of the circumstances. A silver drainage-tube at that time was pushed almost through the wound, and every hope was felt of his ultimate recovery. These wounds I must add were all from Mauser rifles, for which we learned to have great respect.

One thing which contributed to the healthy condition of the wounds was the fact that each man carries a First Aid Package, and many were able to dress their own wounds, or had an ambulance corps man to do it for them on the field.

Mary Gay Humphreys.

Manila, December 15, 1899.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, March 24, 1900.

NATIONAL ASSOCIATION FOR THE PREVENTION OF CONSUMPTION—MEDICAL LECTURES AS HYPNOTICS—CURIOUS MEDICAL ABBREVIATIONS AND INITIALS—OLIVE BRANCH FROM THE FRIENDLY SOCIETIES—WHISKEY AND MALARIA—ATTACKS UPON HOSPITAL MEDICAL SCHOOLS—THE QUEEN'S VISIT TO WOOLWICH HOSPITAL—TAXATION OF HOSPITALS—VICTORIA CROSSES DEMANDED FOR MEDICAL OFFICERS.

The National Association for the Prevention of Consumption has held its first general meet-

ing, with a large attendance, under the chairmanship of the Earl of Derby. Further announcements were made as to the coming International Congress in London next April (1900) which the Prince of Wales will open. In the report of the Council special stress was laid upon the necessity for vigorous measures to repress spitting in public places and inducing public companies to post cards urging all to refrain from this habit upon their premises, as has already been done by the great London & North-Western Railway Company. Dr. Ransom of Nottingham urged the importance of insisting upon the adequate ventilation of public buildings and offices, as well as houses, many of these being admirable incubators for bacilli.

Dr. Nathan Raw of Liverpool took up the isolation of pauper consumptives in workhouses and said that Liverpool has already adopted this measure and established sanatoria for these unfortunates out in the country. The mortality from the disease in the "Black North" is very high, the deaths in Liverpool alone reaching 2000 per annum.

Some comment was made upon the small representation of the clergy upon the Council. Sir William Broadbent explained that several prominent clergymen had been invited to become members of Council at the outset but had declined—a fact which scarcely redounds to the credit or progressiveness of their profession, as all other classes of men are keenly alive to the value of the movement and roused to the dangers of the disease.

There is an excellent story going the rounds in regard to the original establishment of one of the great courses of lectures in medicine at the Royal College of Physicians. It alleges that the founder of the course was a wealthy merchant-grocer who for years had suffered terribly from insomnia. Upon one occasion he had had no sleep for five days and was restlessly pacing the streets in a half-demented condition when he happened to pass the door of the College and see the announcement of an endowed lecture which was then being given. He wandered into the room, took his seat, and in fifteen minutes was sound asleep. So grateful was he that when he awoke he at once proceeded to establish and endow a similar course for the benefit of future sufferers.

There is a singular tendency in English "medicalese" to resort to abbreviations and initials of various sorts, most of which are comparatively unknown among us, in spite of our alleged tendency to clip and shorten everything. For instance a general practitioner is always referred to as a "G. P."; a house-physician or house-surgeon as an "H. P." or "H. S."; a case record of tabes dorsalis is headed with the mystic letters "T. D."; one of general paralysis of the insane, with "G. P. I.," and the same contractions are habitually used in conversation. A unique combination of initials as a diagnosis-endorsement is reported to be in vogue at University College Hospital. Whenever a case which is clearly serious enough for admission proves too complicated or difficult to warrant a precise diagnosis upon the hurried examination of the receiving-room, it is promptly initialed "G. O. K." and sent up to its appropriate ward for adequate investigation at leisure. The mystic characters signify simply "God only knows."

The principal topic of interest at the recent meeting of the Friendly Societies' Congress at Plymouth was the issue raised by the demand of their medical attendants that a wage-limit should be set to their membership. In view of the disgracefully low rates *per capita* allowed for medical attendance, the profession has been most justly demanding that no one should be eligible for membership in the Societies who is in receipt of a wage above a certain amount. To this the Congress was absolutely opposed, but expressed its recognition of the fact that the time had come for a readjustment of the remuneration of their medical officers and reappointed a committee of arbitration to meet a similar body from the General Medical Council to discuss the matter. This Conciliation Board was proposed by the Societies and arbitrators appointed a year ago, but so far nothing has come of it, on account of the failure of the Medical Council to appoint its representatives. While thoroughly endorsing the position of the profession in the matter, it really seems a pity that it should put itself apparently in the wrong by refusing to meet and discuss the question amicably, however little prospect there may appear of getting their just demands granted thereby.

The chronic obstructionist and medical *"advocatus diaboli"* is again abroad in the person, first, of the Secretary of the Antivivisection Society, who has discovered a new and simple preventive of malaria, *viz.*, the avoidance of whiskey, based upon the experience of *one* woman traveler in Africa, and, hence, protests against "experimenting upon living animals with a view to producing an antitoxin!" A combination of infantile credulity and cheerful idiocy hard to improve upon. Second, in the august individuality of the irrepressible Stephen Coleridge who, in the current number of the *Contemporary Review,* produces an appalling mass of statistics in support of the allegation that the wicked hospitals are perverting the funds subscribed by the charitable public to the support of their nefarious medical schools and inhuman laboratories; the only proof being that since certain of these schools have received additions to their general subscriptions of late years, and notably from the Prince of Wales' Fund, their allocations to their medical schools and laboratories have increased as much as two or three hundred pounds per annum in some instances! The explanation being perfectly obvious to any one but Mr. Coleridge that nearly a third of the diagnostic work of the hospital wards is now done in the clinical laboratories of their schools and the amounts allotted represent but a fraction of the actual expense, to say nothing of

the therapeutic value of this most important branch of what we think even he would admit to be the legitimate work of a hospital. Unless diseases are to be treated by direct revelation, accurate diagnosis is certainly of some assistance.

A Federation of Workingmen's Clubs has, however, swallowed the accusations whole and inflicted a lengthy memorial upon the poor Prince of Wales, informing him of the gross abuses which are being perpetrated upon his Hospital Fund, to which they do not subscribe a penny, and begging for a redress of these *their* grievances! Patients are regarded by doctors, forsooth, "as so much material for experiment!"

The event of the week has been Her Majesty's visit to the wounded in Herbert Hospital, Woolwich. This was no mere formal state function for politic effect, although the swarming myriads who thronged the route taken by the royal carriage turned it into a great popular ovation. The Queen refused to have even the customary guard of hussars before her carriage and drove almost unattended through the crowded streets from the station to the hospital. Arrived at the hospital the wonderful old lady was placed in a chair and wheeled slowly through the wards, stopping to talk to the more serious and more interesting cases, to hear their stories, see the bullets they proudly displayed, and present each of them with a bunch of flowers.

The rejuvenating effect of the war upon Her Majesty has been simply astonishing. So strongly has her sympathy been awakened by the sufferings of her soldiers and their families, that, although she had almost completely given up public appearances for years past, an immunity to which her eighty years amply entitled her, she has made two visits, each involving a train-journey of several hours each way, to the great military hospitals within the past few weeks, to say nothing of receiving staffs of hospital ships, sending telegrams of condolence to the wounded at the front, and warmly supporting, both by word and contribution, all the hospitals equipped for the front. The heart of the nation has been warmly touched by this display of womanly sympathy and never was Her Majesty revered and beloved as to-day.

Merit has a good deal to do with promotion in this country even to purely official Court appointments, and every member of the profession will cordially endorse the nomination of Lord Lister as Sergeant-Surgeon in Ordinary to the Queen in place of Sir James Paget deceased, and scarcely less so that of Mr. Frederic Treves to the vacancy among the Surgeons Extraordinary caused by Lord Lister's promotion.

The strait-jacket of red-tape which paralyzes the activities of English officialdom was never better illustrated than by the attitude of the Government toward the appeal of the hospitals to be relieved from the payment of rates, *i.e.*, city taxes. The mere calling of attention to such a monstrous injustice ought to be enough, but Mr. Chaplin, in reply to the delegation which waited upon him, could see nothing but serious complications and legal difficulties about the proposal, although admitting the abstract justice of it. And when the matter was brought up in the House of Commons this week by Sir Cameron Gull, Mr. Balfour, the leader of the Government, while expressing sympathy with the demand, would not even promise to introduce a bill bearing upon the question on account of the difficulties surrounding it, and advised that it be referred to a committee—and thus buried comfortably for the session.

The Army Medical Corps came before the House last week in public debate, and nothing but golden opinions upon its conduct were heard upon all sides. The House and the public are both appreciative of its magnificent services and so are the commanding officers, in word at least, but in one respect these latter gentlemen lag sadly behind, and that is in formal recognition of such services. General dissatisfaction is expressed here that so far no medical officer has been recommended for the Victoria Cross, and the public is getting thoroughly roused to the unfair treatment in this respect accorded in the past, and the action of the generals will be sharply watched in future.

TRANSACTIONS OF FOREIGN SOCIETIES.

French.

TREATMENT OF ANGIOMATA BY INJECTIONS OF COAGULATING FLUIDS—SUCCESSFUL FORMATION OF A NEW NOSE—TREATMENT OF THE GRIP—OBESITY RELIEVED BY A DIET OF SKIMMED MILK—SHOULD THE PLACENTA BE LEFT AT AN OPERATION FOR EXTRA-UTERINE PREGNANCY?—EPIPLOITIS AS A COMPLICATION OF APPENDICITIS.

At the Academy of Medicine, February 27th, Le Dentu spoke of the treatment of erectile tumors, by injections of coagulating fluids. Several precautions should be taken. Some sort of a ring should be pressed down around the angioma to contract the circulation and prevent the escape of forming clots. The ring should be kept in place fifteen or twenty minutes. In this way the danger of embolism may be avoided. From 2 to 40 drops may be injected at one sitting, according to the size of the tumor. The fluid used by Anger for this purpose is made up of 5 parts perchloride of iron, 3 parts chloride of sodium and 12 parts of water. In rebellious cases, one-half a part of chloride of zinc may be substituted for the three parts of chloride of sodium. As the tumor diminishes in size the quantity of injected fluid may be decreased. In many cases a single injection will suffice to stop the growth. The effects of an injection are manifested slowly, so that it is better to wait some weeks before repeating the injection. This method of treatment is perhaps not as satisfactory as electrolysis, especially for angiomata of the face, but it is worth serious consideration, especially by doctors who

have not electrical appliances at their command.

BERGER considered extirpation the best method of treatment for angiomata which are not too extensive. If so, ignipuncture or the galvanocautery should be used, or, better still, electrolysis. The thermocautery is not a good instrument because the extent of its action cannot be known with certainty.

LUCAS-CHAMPIONNIÈRE, however, commended the thermocautery which in his hands, he said, had often produced satisfactory results.

BERGER presented a patient upon whom he had formed a new nose in the following manner: Two flaps, one from either cheek, their bases being in the upper lip at the angle of the nose, were turned over and sutured in the median line, with their cutaneous surfaces directed inward. A third flap, taken from the forehead, was swung around so as to cover the other flaps. Its cutaneous surface directed outward formed the skin of the nose. Between these two layers of flaps was placed a platinum support, resting on the crest of the nasal bones and on the superior maxillary bones. The parts healed primarily, and, as the platinum support was completely included in the tissues without apparent irritation, there was the best reason to hope that the restoration of the nose would be permanent.

HUCHARD advocated the administration to patients suffering from the first symptoms of grip of large doses of hydrobromate of quinine, 15 or 20 grains at a time. The doses of 7 or 8 grains which are usually employed are ineffectual. If there is considerable nervous depression, strychnine sulphate should be administered in doses of $^1/_{60}$ of a grain. A milk diet is of advantage as assuring free renal action.

HAYEM said that such large doses of quinine were capable of setting up a gastritis and doing the patient more harm than good. He did not advise a milk diet for the reason that the grip was almost always accompanied by asthenia, which was sure to be increased if the patient was deprived of his accustomed nourishment and put upon a milk diet.

DEBOVE, March 6th, presented a patient whose weight had been reduced in one year from 147 kilos to 93 kilos (a loss of more than one-third of his weight). At the time of beginning treatment the patient suffered from polyuria and albuminuria and was unable to leave his bed. Exercise was out of the question; Debove had little faith in the reduction of obesity by drugs, and so the patient was put upon an insufficient diet. For a month his daily food was 5 pints of milk. He lost 30 pound in weight. The next month he received only 4 pints of milk daily. He lost 14 pounds. During the next five months he received only 2 pints of milk daily and lost 40 pounds. He showed no further loss of weight even although he was kept upon 2 pints of milk a day. The milk diet was thereupon discontinued and the patient was given green peas and beans, green salads, and fruit as he wished it. In four months he had lost an additional 24 pounds, and at the time of the report he weighed about 185 pounds and had regained his health and strength. Such treatment to be successful had best be carried out in the routine life of a hospital.

At the meeting of March 31st, FERNET said that prophylaxis demanded the isolation as far as possible of those suffering from the grip. Antisepsis of the nose and mouth should also be carried out, as these are the portals of infection. In the absence of any specific remedy, the therapeutic indications are those of toxi-infectious diseases in general. They consist in the best possible alimentation of the patient and the speedy elimination of poisonous products, especially through the kidneys. A milk diet and hydrotherapy best meet these demands. Medication is of secondary importance. For example, the pulmonary congestion with tachycardia, due apparently to weakened action of the pneumogastric, is quickly relieved by the application of cold compresses which may be renewed every hour or every two hours if necessary.

At the Society of Surgery, February 21st, RICHELOT mentioned an instance of successful operation for extra-uterine pregnancy, the placenta being left *in situ* for subsequent absorption. Several other members of the Society commended this practice. HARTMANN alone spoke against it. He said that the placenta ought always to be removed, unless intestinal adhesions or other complications make its removal dangerous.

WALTHER, at the meeting of March 7th, said that in operating 83 times for appendicitis, he had 18 times found adhesions between the omentum and intestines, the upper part of the cecum or the ascending colon usually being involved. Attacks of epiploitis may occur in such cases, even after removal of the appendix. Such adhesions may also cause intestinal stricture or digestive disturbances. Hence, the necessity for the removal of the adherent portion of the omentum.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held Thursday, March 15, 1900.

The President, Wm. H. Thomson, M.D., in the Chair.

The subject for the evening was a continuation of the discussion on cancer.

Cancer of the Breast.—This paper was read by Dr. Robert Abbe. It appears in the present issue of the MEDICAL NEWS. (See p. 521.)

In the discussion Dr. Torek said that three things must be determined as a preliminary to every radical operation for cancer of the breast. First, how much skin shall be removed? Second, to what extent the glands must be dissected out and, third, how much muscle must be removed? Since the publication of Halsted's very favorable results, in 1894, Dr. Torek has always removed both pectoral muscles in all cases of can-

cer of the breast. He has never had occasion to regret it. Among his patients were a number of working-women in whom it might be thought that the function of these muscles would be very much weakened. As a matter of fact, however, their removal injures but slightly a woman's capacity for doing work and patients complain but little of the after-results. The removal of the fascia above the pectoral muscle is practically never sufficient. If the muscle is visibly affected its removal is surely indicated. It must be borne in mind that where there are no macroscopic appearances of the invasion of the muscle by the cancerous process the microscope may reveal the presence of an abundance of cancer-cells.

Removal of Glands.—It is agreed by all operators that the glands into which the cancerous tissue drains must be removed. It used to be considered sufficient to remove the axillary glands only. Some surgeons were satisfied to open up the axilla and remove the superficial packet of glands beneath the skin. They seemed to think that this was all that was necessary. There was no question in their minds of having to remove the glands at the apex of the axilla between the scaleni muscles. There is no doubt that very often, when it is entirely unsuspected and when there are no clinical signs of the fact the glands behind the pectoral muscle are also invaded. These must be removed.

It has become more and more evident that for the sake of avoiding recurrence, the skin over the cancer must be sacrificed. The skin is the foremost organ with one exception in which recurrences of cancer take place. Dr. Torek in his experience has had most cancer recurrences in the pleura, next after this in the skin.

Prognosis of Mammary Cancer.—Dr. Manley said that cancer of the breast is the most frequent malignant growth that comes for operation. Despite the optimistic opinion which has been developing of late years the condition is practically incurable in considerably more than the majority of the cases. Scarcely more than a decade ago Dr. Sands here in New York was so discouraged by his experience in the surgical treatment of mammary cancer that he declined to operate. He seemed to think that the patient was exposed to needless risk without any reasonable hope of benefit to be derived therefrom, certainly without prolongation of life.

There are three things the patients wish to be assured of when they come to be operated on for cancer: First, whether life will be endangered by the operation; secondly, whether it will impair the usefulness of any member, and, thirdly, whether it will be curative. At the present time the mortality has been so much reduced that patients may be at once reassured on the score of danger from the operation itself, although it must be borne in mind that a certain mortality attaches to the operation and patients should not be given too absolute assurance as to its lack of danger. As to impairment of the usefulness of the arm, the modern complete operation undoubtedly does leave the arm much weaker than before, besides, when the glands of the axilla are completely removed, sometimes elephantiasis results. Painful conditions of the arm with loss of power and trophic changes sometimes come as the result of interference with the nerves during the dissection of the axilla. It is doubtful if the present optimistic mood with regard to what is called the complete operation is entirely justified. It must be remembered that after simple removal of the gland in the old days patients frequently lived for three years and sometimes for much longer, even up to nine or ten years. Now, after complete removal of a not very large mammary carcinoma, with all its connecting lymphatics as far as they can be reached, recurrence is not out of the question.

Where local recurrence did not take place Dr. Manley has seen it come in the larynx or in some other of the internal organs. On the other hand, where no attempt is made to remove the lymphatics, recurrence may not take place in these. Dr. Manley has recently seen a case of mammary carcinoma treated by caustics. Recurrence took place not in the lymph glands, but in the other breast.

Delayed Recurrence.—Dr. William H. Thomson said that the citation of Dr. Sands' name recalled a patient whom he had seen eight years ago and who ten years before had been operated on by Dr. Sands for mammary cancer. The operation consisted in simple removal of the mammary gland. Recurrence came in the axillary region ten years after the original operation. The limit of three years, then, for cured cases would seem to have certain exceptions in slow growing cancers.

Cancer of the Uterus.—Dr. Henry C. Coe said that during recent years German surgeons have been very much interested in cancer of the uterus and as a consequence a number of unsettled questions in the matter are under discussion. The important thing with regard to uterine cancer is early diagnosis. As Dührssen says, we must educate not only the practitioner, but the laity, to recognize the early signs of cancer of the uterus so that they may come soon enough for operation. As it is now, less than 30 per cent. of the patients who present themselves in German clinics suffering from cancer of the uterus are operable. In this country it is estimated that not much more than 2 per cent. of the cases are operable when they come to the clinics. Of course, the number of hopeful cases is much larger in private practice. As the result of patients coming earlier for operation the German statistics are much better than the American and English statistics in this matter. At Edinburgh out of some 250 cases of uterine cancer operated on there were only 15 radical cures. Leopold had 17 radical cures out of 76 operations. This difference is not due to the fact that cancer in Edinburgh is different from cancer in Germany, although one Edinburgh surgeon suggested this possibility, but it is due to the fact that the diagnosis is made

earlier, the patients come sooner for operation, and there is a better operative technic.

Symptoms of Uterine Cancer.—It is not necessary to have the classical symptoms of pain, tumor, and foul discharge in order to be able to make the diagnosis of uterine cancer. When these symptoms are present the case is very probably beyond the reach of operative procedures. The important symptom is irregular bleeding from the uterus. The general practitioner, as well as patients themselves, must be given to understand that the approach of the menopause does not justify the existence of irregular bleeding. Where such hemorrhage exists it is always suspicious, especially if the patient is between forty and fifty. If there are no signs of cancer to be found on bimanual palpation a wedge-shaped piece should be cut from the cervix, or the interior of the uterus curetted and the specimens obtained submitted to microscopic examination for the positive decision of the question as to whether cancer exists or not. The existence of irregular bleeding is sufficient of itself to justify operation. There are two things that may lead to an error of diagnosis in this matter. A small fibroid may exist or senile endometritis may cause the irregular hemorrhage. For the fibroid operation would be indicated; if endometritis exists no harm will be done by the operation.

Contraindications to Operation.—The important contraindication to operation is the invasion of other tissues by the cancerous process. In order to decide whether this invasion has taken place or not, the patient should be examined under an anesthetic. Enlarged glands cannot be palpated with any assurance, and they are frequently found after operation in positions where it might have been expected that they could not escape the examining finger. It is important to differentiate between true neoplastic adhesions and inflammatory adhesions. In a case seen recently a patient said that she had been told eight years ago that her cancer of the uterus had gone beyond that organ into the peri-uterine tissue and was hopeless. Nothwithstanding the bad prognosis the woman is still alive, although only a palliative curettement was done at the time. The fixation and infiltration in her case were evidently due to inflammation and not to neoplastic invasion. In general the prediction of the length of life that a cancer patient may have without operation is extremely uncertain. Fifteen years ago Reeves Jackson was so much discouraged with his poor success in operations for cancer of the uterus that he declared that patients lived longer and were almost as comfortable without operation. This poor outlook after operation is no longer justified, although radical successes are still rare enough. Dührssen's statistics are the most favorable and he chronicles less than 10 per cent. of radical cures. This is, however, a decided advance over the former state of affairs, when it was doubtful if any cases were really helped.

Choice of Operation.—As to whether the vaginal or the abdominal route should be taken in operating is a subject that divides surgical opinion a great deal. The vaginal route is growing in favor. Cancer of the corpus uteri will nearly always have to be removed by laparotomy. In very stout or in very weak patients it may be necessary to try the vaginal route even for these cases. For cancer of the cervix a serious question exists as to whether the cervix should merely be amputated or the whole uterus extirpated. Byrne of Brooklyn has done very good work in amputation with the cautery. Moore Madden has also used this plan with success. Byrne's statistics certainly demonstrate that igni-amputation may give radical cure. As a rule, however, better ultimate results are obtained by total extirpation of the uterus. Of late years an attempt has been made to do for cancer of the uterus what has been accomplished by Halsted's operation for cancer of the breast. The idea was to remove all the pelvic tissue that seemed liable to be infected because of the lymph drainage from the uterus. Needless to say this radical procedure adds very seriously to the mortality of the operation. It can only be undertaken in strong, healthy patients. The primary mortality in these cases is at least 20 per cent. The hope of radical cure given by the radical operation, however, seems to justify the added risk. Doubtless, too, the danger of the operation and its mortality and the length of time necessary to perform it will be gradually lowered by improvement in technic and by the acquirement of the special skill necessary for this class of operations.

Palliative Treatment.—This should not be entirely neglected. Despite the spread of knowledge with regard to cancer, a large number of cases still come to the surgeon only when operative measures are absolutely hopeless. For these the use of the cautery or the sharp spoon are clearly indicated. The symptoms are very much relieved and the progressive course of the disease is hindered for a time. The foul discharge, which so often makes life miserable for the patient and so unpleasant for her friends, is completely done away with. It is to be hoped that the education of the general practitioner and of the laity to the realization that irregular hemorrhage is the initial symptom of cancer will bring cases for operation at an earlier period than is now, unfortunately, the case and so make palliative procedures unnecessary.

Prognosis and Early Diagnosis.—In the discussion Dr. Boldt said that the prognosis of any case of cancer depends on its early diagnosis. At times a small nodule in the cervix may have a very bad prognosis because it fails to give atypical bleeding and may spread to the parametrium or even to the ureters before giving any recognizable symptoms of cancer. Only too often when cancer develops in the portio vaginalis of the cervix, it is treated, that is, the symptoms it gives rise to are treated, by douches. In this way the carcinoma is easily allowed to go too far before coming to the surgeon. Irregular bleeding must

at any period of a woman's life be a cause of suspicion as regards cancer. And this is especially true at the time when the menopause approaches. Between thirty and thirty-five cancer of the uterus is by no means rare. When it occurs in these younger women it has an especially unfavorable prognosis. In the succulent tissues the carcinoma grows rapidly and is carried widely by the lymph stream. To secure sufficient material for the microscopic diagnosis of cancer of the uterus it is not enough to make a few scrapes with the curette. Every vestige of the uterine mucosa should be removed. Care should particularly be taken to carry the curettement well up into the cornua of the uterus, otherwise the specimens are liable to be a source of error and false security, rather than any assured aid to the diagnosis. Erosion and ulcer of the cervix should be looked for very carefully. True ulcer is very rare. Where erosions exist portions of tissue should be removed for microscopic examination. Such specimen should be submitted only to a competent pathologist, that is, one who has had considerable experience in examining tissues for malignancy. A false report of non-malignancy will almost surely involve a delay of four to six months and then the cancerous process will be advanced too far for operation. As a rule, forcible dilatation of the cervix is uncalled for and it is amply sufficient simply to introduce the curette. Curettement should not be attempted without an anesthetic, however, as it is impossible to do it effectively. The principle contra-indication to operation is the existence of extension of the cancerous process into the peri-uterine tissues. The existence of such peri-uterine involvement can only be decided by a rectovaginal examination. After some experience one is able to differentiate inflammatory from cancerous infiltration by the greater resiliency that is noted in inflammatory adhesions. Inflammatory material also has a more even feeling. Malignant infiltration gives a boardlike sensation that is rough and at times almost nodular in character.

Igni-Operation.—The use of the cautery for the extirpation of cancer is undoubtedly an excellent procedure. Mackenrodt's statistics of igni-extirpation of the uterus have often been criticised. When the cases, however, which Mackenrodt deliberately took for operation are considered, his results do not seem so bad. He took some of the worst cases in his practice and yet many of them lived for three years. Dr. John Byrne of Brooklyn has undoubtedly done good work in the development of the technic of the use of the cautery in operations for cancer of the uterus, and this method of treatment has undoubtedly an encouraging future.

Prognosis According to Age.—Dr. W. Evelyn Porter said that age is an important element in the prognosis. The most satisfactory results of operation are obtained in patients past fifty years. In them, even where some malignant infiltration of surrounding tissue seems to exist, a radical cure is sometimes effected by operation. Between the ages of thirty and forty radical operation is most difficult. In the comparatively young tissues the cancer spreads rapidly, very soon involving parts distant from the uterus. Besides the blood supply is at high tide and many more bleeding vessels must be cared for than later in life. The prognosis of these cases, then, is much worse than that of older patients. Vaginal extirpation seems preferable in all cases to amputation of the cervix. For cancer of the corpus uteri the operation by the abdominal route seems more suitable. But even for this, operations through the vagina are being done more and more frequently.

Difficulties of Diagnosis.—Dr. Philander Harris of Paterson, N. J., said that the greatest hindrance to early and assured diagnosis is the disturbance of menstruation brought on by the menopause. In physician's minds, as well as among the laity, there is an impression that all sorts of disturbance of menstruation may be caused by the menopause. Change of life seems the satisfactory explanation for almost any anomalous hemorrhage that may occur between 35 and 55 years of age. It is not an unusual thing to have women state after having menstruated from ten to fourteen days that they did not think this a serious symptom, because they were under the impression that the change of life had something to do with it. Dr. Harris saw a farmer's wife recently who had had a show of blood daily for nearly a year. She did not think it worth while to consult a doctor about it, because she thought it due to the change of life. When such erroneous impressions are removed it will be possible to make early diagnosis of cancer of the uterus. The microscopic diagnosis of cancer is after all only an aid in these cases. It must not be considered as the ultimate criterion. All the circumstances of the case must be taken into account in making the diagnosis. The outlook in operations for cancer of the uterus is certainly much better than it was twenty years ago. The abdominal route with thorough dissection of all suspected tissues is especially encouraging. It adds to the mortality but the ultimate results would seem to justify it. Dr. W. Gill Wylie said that cancer attacks only degenerate tissue, hence the greater liability of the breasts and uterus to suffer from it and especially at the time of involution. It occurs in other organs that are especially liable to injuries or irritation during their normal function. The best prophylaxis of cancer consists in the prevention of all possible sources of irritation in organs that are especially liable. Lacerations of the cervix should be repaired, subinvolution should not be allowed to persist, in general, all chronic irritative conditions should be terminated as soon as possible. Cancer is apt to be very rapid in the young, that is in people in the fourth decade of life, so that suspicious symptoms should be traced to their origin without delay. The almost pathognomonic symptom of uterine cancer after forty is the stoppage of regular men-

struation for a time and then its recurrence. The longer the intermission between the cessation of menstruation and its renewal, the more certain is the recurrence a symptom of a cancer. This is very well known generally, yet the lesson is neglected often for weeks and months right here in New York. The poor results in hospital practice after operations for cancer of the uterus are due to the fact that patients come only when hopeless. With the improvement in technic there is every reason to think that the statistics will be better. The mortality of the abdominal operation should not exceed 2 per cent. Cancer of the body of the uterus is the least dangerous type and the most satisfactory for operation. Cancer in this location occurs more frequently than is usually thought.

Suppuration Beneficial.—There is a practical fact of very great importance, the reason for which is unfortunately unknown, but which has been observed by too many surgeons to be merely a false impression. It is that suppuration after operation for cancer appears not infrequently to be of advantage. In a certain number of cases where the operation promised surely to be a failure, because all of the cancer was not removed, suppuration supervened after operation and destroyed tissue that had been left at the time of operation. Palliative treatment, with the curette and applications of chloride of zinc, after cutting away all possible tissue with the scissors, often gives most satisfactory results as far as regards the limitation of symptoms. This form of palliative treatment seems to be better than the use of the cautery.

In closing the discussion, Dr. Coe said that the microscope in skilled hands undoubtedly is of the greatest service as a final test in doubtful cases. Dr. Cullen of Baltimore, in his paper read not long ago before the New York County Medical Society, said that in all the cases examined microscopically during the last five years at Johns Hopkins Hospital not a single mistake had been made, although surgeons and pathologists were intent on testing this method of diagnosis to the last degree.

German authorities are of the opinion that the abdominal route is preferable for operations for cancer of the uterus. For small tumors certainly the vaginal route seems better. The important thing to be remembered, with regard to mortality after all operations for cancer and their ultimate success, is that if patients come for operation in the initial stage the mortality will surely be very low and radical cures much more frequent..

THE NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held Monday, March 19, 1900.

The President, Frederick Holme Wiggin, M.D., in the Chair.

Dr. Wiggin reported a successful case of excision of the cecum with end-to-end anastomosis for a non-malignant growth which, as a result of long continued and recurrent attacks of appendicitis, had completely occluded the bowel.

Symposium on Serum-Therapy.—Dr. E. K. Dunham reviewed the theory of immunity and of serum-therapy as it has been developed during the last few years. Ehrlich's theory is the most complete and also the most satisfactory explanation of the phenomena that are observed during the development of immunity and during the therapeutic application of various sera. Ehrlich assumes that there exist within the cell very large molecules, such as the recent development of organic chemistry has made us familiar with. These may be modified by substitution of simple elements, or radicals, or groups of elements, or by cleavage. This process of change gives a large field for alterations within the cell without actual destruction of its life. The complex substances produced by bacteria act as poisons by causing changes in the chemical constituents of the cell which embarrass its physiologic action without necessarily killing it or causing such functional disturbance as would give rise to noticeable symptoms. These toxins interfere with intracellular metabolism. The effort to overcome this interference gives rise to functional hypertrophy. A certain amount of reserve matter is assumed to exist in all organisms and in all of their cells. The development of this reserve matter up to a certain stage enables the cell to protect itself for the time being and when a large amount of the reserve matter is called into play the self-protective quality may become enduring. This is immunity. An animal may be naturally immune not only to the poisons of bacteria, but also to other poisons. It is well known, for instance, that atropine does not affect the rabbit.

Theory of Antitoxin.—When cells fail to be acted on by substances that ordinarily affect cellular function, there is presumed to be an absence in the cell's intimate chemical constitution of certain side-chains of molecules that exist in conjunction with the fundamental substances that make up the essence of the cell. Where these side-chains of molecules do not exist, the cell, not being affected by a poison, none of its reserve matter is called into play and so no antitoxin is formed. For antitoxin is a solution in the serum of certain neutralizing substances that are formed in the cell as the consequence of irritation calling its reserve force into play. An excessive dose of toxin paralyzes all cellular activity and so there is no production of antitoxic substances. Irritative doses, however, influence the side-chains of molecules in the cell, but more of them are called into being from the reserve matter and so antitoxin is produced. Thus it is that usually animals which are most highly susceptible to a poison produce the best antitoxin for that poison when it is administered only in irritative doses for a period of time. Not all the cells of the body are equally affected by toxic substances. Thus it is that special cells are particularly involved in the production of certain antitoxins. Tetanus

acts particularly on the central nervous system. It is only in the brain and cord that the special side-chains of molecules exist which are acted upon by the tetanous toxin. These cells partly neutralize the toxin of the disease but are, as a rule, finally overwhelmed by it. That these cells do neutralize some of the tetanus toxin is proved by the fact that even outside the body they are able to produce this action of neutralization.

The side-chains that are affected by the diphtheria toxins exist especially in the lymphoid material of the body, *i. e.*, in the cells of the bone-marrow and of the lymph-glands. And it is to these cells particularly that we owe the production of the diphtheria antitoxins. It must be remembered that other toxins besides those due to bacteria can produce antitoxin. Ehrlich's experiments in this matter with abrin and ricin are familiar to all. Natural immunity to infection does not include immunity to the toxin of a disease. There are observations which demonstrate that the body cells may be able to protect themselves from infectious germs, and yet the organism be affected by the toxins of these microorganisms if in some way they should gain an entrance into the body. It is possible to produce antitoxins which may protect from the toxins of a disease and yet not insure immunity from infection. Certain observations seem to show that a diphtheria antitoxin produced by the injection of living bacilli into an animal is both anti-infectious and antitoxic; that is, it protects against the disease itself and against the toxins of the disease. Diphtheria antitoxin produced by the injection of dead diphtheria bacilli protects only against the toxins of the disease, but gives no immunity from infection.

All the theories in this matter of immunity and of the action and production of antitoxins are as yet merely suggestive and are by no means possessed of any definite scientific certitude. Clinical experience is needed to substantiate certain parts of the theories now advanced and give them an assured basis of scientific truth.

Preparation of Tuberculins.—Dr. E. A. De Schweinitz, Chief of the Biochemic Division, Bureau of Animal Industry, United States Department of Agriculture, Washington, D. C., explained the preparation and use of the old and new tuberculin. The old tuberculin was obtained from beef bouillon to which glycerin had been added, the tubercle bacillus being allowed to grow upon it for a number of weeks. The bouillon culture was filtered of all germs by means of a Pasteur filter and then concentrated, being heated to a temperature sufficiently high and for a sufficient length of time during the concentration process to assure the death of all living germs.

The new tuberculin is an extract only of a virulent culture from the surface of the medium without any of the culture medium itself mingled with it. The basis of it consists, therefore, of the cells of the tubercle bacilli. An extract of these cells is made with water and glycerin. The bacilli are ground up previous to the making of the extract, so that the substances within them may be extracted more completely. Certain chemical compound within the cell-walls of the bacteria cannot be extracted unless the cells are broken up.

Therapeutic Value.—Sattler found that guinea-pigs and chickens inoculated with tuberculosis lived much longer when tuberculin was administered to them than when it was not. Prof. Brieger, Koch's assistant in the department for infectious diseases at the University of Berlin, said at the recent Congress for Tuberculosis held in Berlin that the old tuberculin was not without its usefulness, but that doctors were not patient enough in its employment. It is curative for most cases of lupus and is a most valuable aid for diagnosis in animal and human tuberculosis. In 1154 cases of tuberculosis in Berlin during the last five years, tuberculin has been the decisive test. These cases occurred among 2500 patients in whom there were no distinct physical signs.

Specific Toxin of Tuberculosis.—The product of the bacillus tuberculosis which causes the necrotic changes in tissues affected by tubercle bacilli is soluble in water and has been the subject of considerable study during recent years. This substance must probably be considered as the specific toxin of the tubercle bacillus. It is this necrotizing substance which produces the characteristic pneumonia of pulmonary tuberculosis. It is by this pneumonic process that the bacillus seems to protect itself from the action of the phagocytes in the human system. Despite all that has been learned in recent years about tuberculous toxins, Koch's new tuberculin does not seem to produce any better results clinically than did the old tuberculin. The medical profession throughout the world generally is a unit with regard to this conclusion.

Serum-Therapy of Tuberculosis.—The theory that the serum from inoculated animals possesses in tuberculosis, as in so many other infectious diseases, an antitoxic property has been a favorite one. It is certain that such antitoxic properties are developed to any appreciable extent only several years after the original inoculation. Some results in the use of tuberculous serum, that is antitoxin, have been very encouraging. The whole subject is, however, still in an experimental stage. Judgment must be suspended until the results of investigation now under way have been definitely brought out.

Antipneumococcus Serum.—Dr. Alexander Lambert said that as the pneumococcus causes 90 per cent of all pneumonia it is very desirable that we should obtain if possible a serum to counteract its effects. Even if the pneumococcus serum did not have such markedly antitoxic properties as the antitoxins of diphtheria and of tetanus, it would still be of distinct aid if it favored the action of the leucocytes. All the pneumococcus serum employed so far has had its action within the blood-vessels. This serves to counteract any septicemia that may be present because of the absorption of toxic substances from the pneu-

monic areas in the lung. The sera, however, do not cause degeneration of the exudate within the lung alveoli and so do not bring the pneumonia to a termination sooner than it would normally come. The pneumococcus produces a toxin which has not so far been isolated. Animals die from the absorption of this toxin by a species of septicemia. In animals, then, the pneumococcus serum gives good results. With regard to the pneumococcus, it must not be forgotten that just as there are several varieties of streptococcus, so there are more than one variety of the diplococcus pneumonia. An Italian experimenter has noted that a serum produced by him was active against four varieties of pneumococcus, but not against a fifth.

The serum from dogs, rabbits, and human beings recovering from pneumonia have all been used with unsatisfactory results. Panc's donkey-serum has given the most encouraging statistics in the treatment of pneumonia. In alcoholic patients and where pneumonia occurred epidemically, it has been given with very satisfactory results. Fanoni reports six severe cases in which the serum was given intravenously, as is recommended in these cases, and but one death occurred. There was no crisis, distinct improvement occurred very shortly after the administration of the serum, and the termination was by mild and undisturbed lysis. The only death reported was in a case complicated by pericarditis. The only objections urged against the serum are made on theoretic grounds, and by those who have not used the remedy in practise at all.

Dr. Lambert has used an antipneumococcus serum prepared from the horse in twelve cases. Nine of the patients treated with it recovered. The administration of the serum did not prevent the development of an empyema in one of the cases. In an alcoholic patient, suffering from severe double pneumonia, it seemed to have an excellent effect. In two other alcoholic patients it seemed to do absolutely no good. On the whole this form of serum does not seem to be of any very distinct benefit in the treatment of pneumonia.

(To be Continued.)

REVIEWS.

Proceedings of the American Medico-Psychological Association of the Fifty-fifth Annual Meeting. Held in New York, May 23-26, 1899.

THE activity of this body is well attested by the number, range and high scientific value of the papers here collected. The annual address on some "Problems of the Alienist," by Dr. Frederick Peterson, is worthy of a wide reading. E. Cowles here presents an able paper on the progress of clinical psychiatry. He shows very clearly the drift in modern psychiatric teaching. Imagination and its relations to mental disease is well handled from the psychological standpoint by R. H. Chase. Other papers, by E. C. Runge, W. A. White, and S. B. Lyon, and many others, are of special interest.

The Principles of Treatment and Their Application to the Practice of Medicine. By L. MITCHELL BRUCE, M.D., F.R.C.P., Lecturer on the Practice of Medicine in Charing-Cross Hospital, London; Examiner in Medicine, Royal College of Physicians, London. Revised to conform with the U.S. Pharmacopœia by E. Q. THORNTON, M.D., Jefferson Medical College, Philadelphia. In one octavo volume of 625 pages. Lea Brothers & Co., Philadelphia and New York.

IT was a happy idea of Bruce to write a book to guide the young practitioner; and so well has the plan of the work been carried out that the older physicians may also derive much benefit from its perusal. The book consists of two parts, the first being devoted to the principles of treatment, the second to the application of these principles to various diseases. As well stated by the author: "It starts by assuming no therapeutical laws, but proceeds to find them in the familiar facts of etiology, pathological anatomy and the clinical character of disease. They are carefully examined for the elementary principles of treatment and in the course of the enquiry the student is taught how he may himself employ his observations as guides to practice. Having mastered the most simple therapeutical principles, the reader is led up to higher generalizations, which relate to the nature of disease and its proper relation to treatment."

Thus clinical indications are established which not alone include the routine methods of treatment, but also the actual factors which the physician must encounter and consider if he would intelligently treat not a case, as is so unfortunately the rule with so many young and old practitioners, but a human being who is sick from a definite disease. All the resources of medicine such as hygiene, dietetics, hydrotherapy, climatology, etc., are discussed as well as drugs. Even the personal factor is discussed in a separate chapter. The pictures of diseases as they actually occur, the various indications which may arise, the many things which ought to be attended to and the equally important things which ought to be avoided are all most graphically described. The actual directions as to the exact plan of treatment constitute very sound medicine; the prescriptions, while numerous, are all chosen with distinct reference to definite indications. It may be added that they are adapted to both the British and United States Pharmacopœias. The index is complete and practical.

In short, the book fills a long felt want, and fills it admirably. The publishers' work leaves nothing to be desired, since the typography and paper are excellent and the size of the book is not bulky.

VOL. LXXVI. NEW YORK, SATURDAY, APRIL 14, 1900. NO. 15.

ORIGINAL ARTICLES.

TWO CASES OF RECURRENT TUBAL PREGNANCY.[1]

BY PHILANDER A. HARRIS, M.D.,
OF PATERSON, NEW JERSEY.

Case I.—MRS. W. J. B.; first child born in 1888; second in 1892; third in April, 1895; no miscarriages. On September 16, 1896, after an interval of six weeks since her last menstruation, she was attacked at one o'clock in the afternoon with very severe pains in the abdomen. There was constant pain extending from the pelvis to the lumbar region, with frequent colic. These symptoms subsided, after a continuance of three hours, and were followed by a great deal of soreness over the low part of the abdomen. In four hours after the beginning of the pains she was so much better that she sat up in a chair, and in less than nine hours from the beginning of the pains, she returned in a carriage to her home, a distance of over a mile. The patient described the colicky pains of this attack by comparing them with the gripings of an attack of diarrhea, from which she had previously suffered. While the colicky pains continued she had almost constant nausea, but not any vomiting. On Thursday, September 17th, she still had slight abdominal soreness, but not any colicky pains, was up most of the day, and did some housework. She continued to feel pretty well until six o'clock Friday, September 18th, when the colicky pains returned with great severity, continuing about one hour, with constant pain between the colics. This left her with much abdominal soreness. She had to be helped to bed, after which she rested very well all night. On Saturday, September 19th, some soreness continued in the abdomen, and she also had a constant suggestion of nausea. She rested well on Saturday night, dressed herself on Sunday morning, September 20th; but remained in a chair or on a couch all day. She retired at eight o'clock in the evening and was awakened at ten o'clock by terrible pains; when these pains had continued a short time, her sister arrived and exclaimed to her husband, in the presence of the patient, that she was a "dying woman." The patient has only an indefinite recollection of much that transpired from this hour, until after she recovered from the abdominal section seventeen hours later.

Her physician, Dr. R. M. Curts, first saw the patient at eleven o'clock P. M., September 20th, after the beginning of the most severe colics. The abdomen was slightly bloated; she also vomited frequently from this time until after operation. Dr. Curts found her pulse to be 120; temperature 99° F. He visited her again at four o'clock in the morning, September 21st; her pulse was then 130; her temperature 97° F.; she was very pale. I saw the case, eight hours later, at noon, with Dr. Curts. Pulse then more rapid than in the morning, temperature still 97° F. She was removed to the Paterson General Hospital for abdominal section. Upon reaching the hospital she was taken directly to the operating-room; her pulse was then 160 to 170, and could scarcely be counted at the wrist. Upon opening the abdominal cavity we found it to contain pounds of clots and pints of blood; no fetus was discovered; all bleeding points were tied, the cavity cleansed and the incision closed. Normal saline solution per rectum, strychnine subcutaneously, hot-water bottles, and other restorative treatment used in such cases, were employed in this case. The patient made an uninterrupted recovery, leaving the hospital in twenty-five days after operation in a condition of health.

I feel greatly chagrined to find that I have no written record of the side on which this gestation occurred. The patient did not refer her pains to either side particularly. My inability to definitely determine this matter robs this case of much of its interest. It has been my custom, as those who are associated with me know, to keep full notes of cases and also of operations; this forms a most unfortunate exception to my regular habit.

Second Attack.—Excepting two spells, in the spring of 1897 and 1898, she menstruated regularly until and including March 24th, 1899. She did not menstruate during the following April and saw no menstrual blood until about May 5th, when there was a slight show. While working in her garden at eleven o'clock in the morning that day, she was taken with colicky pains and general soreness in the abdomen. She went into the house and rested for an hour or two, after which the cramps ceased, leaving only a very slight soreness of the abdomen. In the afternoon she resumed her work in the garden and had no recurrence of pains until Saturday, May 20th. She then had slight colicky pains and some abdominal soreness. She remained in bed until the following Tuesday, May 23rd, when she walked two or three miles. From that time she felt quite well until Tuesday, May 30th, when the colicky pains returned, although they were by no means severe. She then again had a slight appearance of blood at the vagina, the first since May 5th. Dr. James M. Curts, brother of Dr. Curts before-named, saw her on

[1] Reported to the Section on Obstetrics and Gynecology, New York Academy of Medicine, February 20, 1900.

that date. She remained in bed, off and on, until July. From May 30th until July she saw blood at the vagina almost daily, with many clots, which were preceded by pains. On Wednesday, June 21st, she was curetted by her physician, Dr. R. M. Curts, without relief from the metrorrhagia. Between June 21st and July 2d, the patient discovered a tumor rising out of the pelvis, somewhat to her left side, which, she says, became rapidly larger. Notwithstanding the rapid development of this tumor, she neither experienced pains nor abdominal soreness; in fact, she had felt much better after the curettement of June 21st, and was out of bed more. I first saw the patient with Dr. R. M. Curts on July 2d. Regarding the case as a recurrence of tubal pregnancy, an abdominal section was proposed, and done on the day following.

Upon opening the abdomen some blood was found in the abdominal cavity, and a thin-walled hematoma, larger than a child's head, with a broad base rising over the right horn of the uterus. Bleeding points were tied, the abdominal cavity cleansed of blood, and the operation completed. The patient made a good recovery, leaving the hospital seventeen days after operation, in a condition of health. She remains well.

Case II.—Mrs. M. A. F., aged thirty-three years; married thirteen years; one child eleven years old; no miscarriages. She menstruated every four weeks, excepting on one occasion five or six years ago, when she went ten days over time. Her menstruation usually lasted five days, was free from clots, normal in amount, and, at

Fig. 1.

Case I. Hematoma showing how the tumor which originated from right side gave greatest prominence on left side.

times, was accompanied with slight pains on the first or second day.

On March 6, 1899, when twelve days overdue, she flowed about the usual amount, normal in character, and for six days, but with much pain in her right iliac region. The sitting position caused pains in the pelvis, and it hurt her for weeks following to sit down; and, indeed, until after the operation. On March 16th, she began to flow again, and this continued four or five days with colicky pains; these colicky pains were always referable to the right iliac region. She was first seen by Dr. Ventura Fuentes, of New York City, about March 21st. She then had a great deal of soreness over the lower abdomen, with pain on her right side. She was out of bed a part of every day and did a little housework. The colicky pains were so frequent and severe that morphine was often taken for their relief. Blood appeared from the vagina again,

Fig. 2.

Case II.—Fetus of first tubal pregnancy.

March 26th, and continued until March 30th, when clots appeared for the first time. From March 30th until April 28th, when she entered the hospital, she flowed almost daily and passed many clots, the colicky pains continuing. At no time was she free from bloody discharge for two days in succession. The worst pains experienced occurred on Sunday, April 23d, when they were most agonizing, and continued for a number of hours. From that time onward the pains were frequent in the daytime and often awakened her in the night. They were all referable to the right side. For two or three days before entering the hospital, she fainted on several occasions, wanted to be fanned a great deal, and had nausea for one entire night. Admitted to the hospital April 28th. Pulse 88; temperature 99° F.

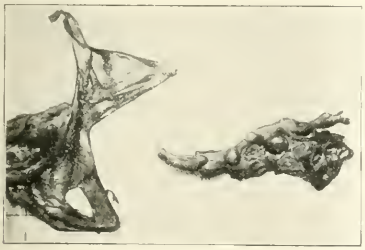
I attempted to operate on this patient by the vaginal route, but was unable to control the hemorrhage in that way, and at once resorted to suprapubic section. On making the preliminary vaginal section the small fetus (Fig. 2) appeared, accompanied by a great many clots, and blood which drained from the abdominal cavity. After making the suprapubic section the bleeding points were tied with catgut, the abdominal cavity made clean, and a gauze drain placed through the cul-de-sac of Douglas into the vagina. The patient made a good recovery, and was discharged from the hospital, cured, twenty-two days after operation.

She menstruated regularly for six months until the recurrence of ectopic gestation.

Second Attack.—On December 24, 1899, after a period of thirty-eight days since her last regular menstruation, the patient had a flow of blood greater in quantity than a normal menstruation which persisted six days. It was fluid in char-

acter, except on January 30th, when clots appeared. On January 1, 1900, she was taken with severe pains, first in the left lumbar region, which very shortly ran through the left iliac region, and became central in the hypogastrium. These pains began at 7:30 in the evening and were uninterrupted and most severe until 11:30 that night. During that seizure she vomited twice. At midnight the pain subsided and she slept lightly for the remainder of the night. After January 1st she did not have any severe pains, but she had slight pains in her left iliac region many times a day and a great deal of pain low in the sacral region until after operation. She also had soreness across the abdomen on January 2d, 3d, and 4th. The flow of blood appeared again from the vagina on January 4th and lasted a day and a half. On January 5th, when I first saw her, she complained of a great deal of pain in her left shoulder and in other parts of her body. She then had a little pain in her left side, and some tenderness over the lower part of the abdomen: pulse 88; temperature 99° F. She was removed to the Paterson General Hospital January 6th. She then had a brownish dis-

Fig. 3.



Case III.—Left tube from which abortion occurred in second tubal pregnancy.

charge from the vagina and slight pain in the left side of her pelvis. She was etherized on January 7th and was found to have a uterus slightly larger than normal. The left tube very much enlarged, especially at its fimbria. Nothing abnormal discoverable to the right of uterus. Pulse 90; temperature 99° F. From this time until January 15th the patient was fairly well and had only slight pains in the left pelvis. She was rather better every way, with pulse about 90, and temperature about normal. I then reëxamined her without the aid of an anesthetic. I found to the right side of her uterus a rounded tumor less than three inches in diameter, and on her left side a tube, probably not larger, or in any way different from that described in my examination of January 7th. I then performed an abdominal section. A large amount of blood was found in the peritoneal cavity, with clots adhering to a ruptured left tube. The left tube was removed; also the rounded tumor, which proved to be a very thin-walled exudation cyst of the right broad ligament, containing colorless serum (see Fig. 3). This small tumor I regarded as secondary to the condition on the left of the uterus. The patient made a rapid and uninterrupted recovery, leaving the hospital in a condition of health twenty days after operation.

Cases of ectopic gestation recurring in the same individual are no doubt rare. I regret that I have not found time in this relation to search literature for reports of cases. Aside from a case, which was a recurrence in the right tube, reported by Dr. Henry C. Coe to the American Gynecological Society in 1893, I am able to refer only to the three following cases which I quote from Dr. Kelly's Operative Gynecology: One case by Dr. Taylor, of Birmingham, England; one case reported to the Berlin Obstetrical and Gynecological Society by Olshausen in 1889; and one case by Herman.

In Taylor's case the two gestations occurred in the right tube. At the first no operation was done and the diagnosis was based on the formation of a hematoma at the time of rupture and the finding of an old scar in the tube which was removed at the operation at the time of recurrence. Olshausen exhibited a living child of right tubal origin and in a little more than one year he operated on the woman for a ruptured left tubal pregnancy of five weeks' duration. Herman operated for a ruptured tubal pregnancy and there was later diagnosticated an unruptured pregnancy on the opposite side.

My first case probably had a recurrence of ectopic pregnancy and in the stump of the right tube which I believe to have been the side on which the first pregnancy occurred. My second case had her first pregnancy in the right tube and her recurrence in the left tube.

RECENT ADVANCES IN THE TREATMENT OF INSOMNIA.

By REYNOLD WEBB WILCOX, M.A., M.D., LL.D.,
OF NEW YORK;
PROFESSOR OF MEDICINE AND THERAPEUTICS IN THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; PHYSICIAN TO ST. MARK'S HOSPITAL.

At the Montreal meeting of the British Medical Association in 1897 I presented a paper on the treatment of insomnia, afterward published in the *British Medical Journal*. In that presentaton of the subject I took the occasion to rehearse the results of work done by the most conspicuous investigators as providing the data from which we might arrive at the construction of a working hypothesis of sleep phenomena, whether natural or induced. This preliminary work I then supplemented by brief sketches of certain of the hypnotic agents then new or most commonly accepted, and endeavored to indicate how each bore upon the sleep hypothesis which was offered.

In the present paper, which I design to make much more brief, I have set before myself the purpose of supplementing my former paper and continuing its deductions to the present date.

Sleep is as essential as food, therefore we must have at our command means of inducing it which are safe, reliable and pleasant in their action. This statement is conditioned by our knowledge or our estimate of what insomnia really is.

Insomnia is a symptom, the result and not the cause of cerebral affections. Our rational treatment is, therefore, to seek out the cause of this symptom and to apply our efforts to the relief of that cause, not vaguely to attack the mere symptom iself. In its relation to pathological conditions we know insomnia to appear as a symptom of various habits, such as alcohol, coffee, and tobacco; in this guise relief from the symptom comes most reasonably from the eradication of the causative habit, and hypnotics are needed but rarely and then only as a temporary measure. In the line of cases where insomnia is symptomatic of pain, the relief of the pain is the proper course, and where that is impracticable it is not a hypnotic to which we should have a recourse but a narcotic. Similar examples will so readily suggest themselves that I need not recite them. In the treatment of any case in which insomnia is the patent symptom we should first seek out and remove the cause; then exhaust the possibilities of physical therapeutics; and then, and not until then, do we arrive at a place which drugs, and drugs alone, can occupy. Here we encounter two lines of treatment which are to be avoided; the first is routine prescribing, which is utterly indefensible; the second is the reckless administration of drugs. Remember that insensibility is not sleep, and it is sleep which we aim to secure, not insensibility. Our logical theory of the treatment is to consider, not how much of any hypnotic agent can be administered with safety, but how little will induce a sleep approximating in depth, duration, and peace the normal slumber. We are to bear in mind that sleep is a phenomenon which we are not to compel but to persuade.

Before we can proceed to the examination of any hypnotic it is necessary to consider how hypnotics act, and that consideration must rest on the theory of sleep-phenomena.

When we reflect that sleep occupies in the main one-third of all human existence, it is surprising that it has been so little studied. Were we to view in a broad way this globe of the earth at this moment, or at any moment of time, we should find the line between the sleeping and the waking of all life as sharply drawn and as clearly defined as the boundary of the light and the darkness on the face of the moon.

In such study as has been given to the subject three main theories have been advanced; two have been for the most part set aside as not accounting for the whole phenomenon, yet each has contributed to the third. The detailed review of these theories has been presented in my preceding paper, and I will not now refer to more than a summary of the earlier ones.

The first of these theories is that sleep is due to cerebral anemia, for which several methods of causation have been proposed. How entirely this theory is inadequate in explanation of sleep will appear when the anemia theory is pushed to its logical conclusion, namely, the production of an undoubted anemia by considerable loss of blood; here hemorrhage should, in accordance with this theory, be followed by sleep, yet we all know of the wakefulness which is the real result.

The second is the chemical theory of sleep. If we follow the investigators who have pursued this hypothesis we find them examining the action of oxygen and of lactic acid, others the effect due to katabolism, and, finally, we reach their conclusion that the volume and the contents of the brain-cells diminish as a result of fatigue. This theory is a forward step, for it brings us nearer a working hypothesis of the action of hypnotics.

Out of these theories we have come to the present theory of the neurons, which, far better than its predecessors, explains many of the physiological phenomena of sleep. From its importance to our inquiry I shall cite the briefest presentation of this theory, that of Dercum. "The cortical cells in the motor area have processes extending toward the surface—dendrites—and a protoplasmic process extending downward through the white matter of the brain, the internal capsule, the crus, the pons, the medulla, and into the spinal cord, where it terminates in a brush-like extremity, the end-tuft. Here it has a certain relation with the motor cells in the anterior horn of the cord, probably one of contact, although that is not definitely known. If the nerve-cells retract, this contact is broken; if the abnormal constriction of the process is relieved for the time being, contact once more takes place." Evidently, I may add, if the neurons are functionally active the dendritic processes must be in contact, for without this consciousness is impossible. When the nerve-cells are exhausted by physiological fatigue, or artificially by drug-administration, there is every reason to believe that their volume shrinks, and it is, therefore, more and more difficult for them to remain in contact. When relaxation comes the processes retract and unconsciousness, *i. e.*, sleep, supervenes.

We have now to consider what drugs will safely and reliably produce this dendritic retraction, and which are tolerable to the patient.

Leech has shown that the alcohol radicles, of which ethyl and methyl are typical, depress the functions of the higher cerebral centers, and that chlorine more than the alcohol radicles is depressant of the lower centers. These facts, then, give us the root of our theoretical hypnotic. To reach both the higher and the lower centers, it must associate with one of these alcohol radicles a sufficiency of chlorine. From this somewhat restricted class we must in practical therapeutics exclude such agents as depress the circulatory system or derange the digestive tract.

Permit me to sum up tersely the requirements in a hypnotic which shall approximate as closely as possible the theoretical agent. It must com-

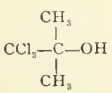
bine one of the alcohol radicles for the action in breaking contact of the dendritic processes with chlorine to affect simultaneously the downward protoplasmic processes; it must be free from depressing action on the heart and blood-vessels, it must not derange the assimilative system; it must be safe; it must be reliable, and it must be palatable.

In my Montreal paper, to which this is a supplement, I discussed a short list of the newer hypnotics which seemed to meet a majority of these requirements. To that list I wish to add the only new hypnotic which has attracted marked attention, chloretone, which meets so completely each one of these requirements as to present itself as a very close approximation to the theoretical hypnotic of which we have been in search. Curiously enough, it closely fulfils the prophecy which I then made as to the chemical composition of the ideal hypnotic.

It will simplify the examination of this product, for which we are indebted to Houghton and Aldrich, if we say at the outset that the coal-tar derivatives are found to be depressant of the circulatory system; that the opium extractives are, whether we find them to be narcotics or hypnotics, damaging to the functions of the digestive tract. These two groups are, therefore, for these reasons to be excluded from the search for an approximation toward our theoretical hypnotic.

Chloretone is a derivative of chloroform and acetone, and is also known as acetonchloroform; it is chemicaly described as a trichlor-tertiary-butyl-alcohol. When caustic potash is gradually added to equal weights of chloroform and acetone a reaction ensues which results in this new substance, which is isolated by steam distillation for the removal of whatever of the two principal substances may be found to exist. Having been cooled, after the removal of water by melting, it appears in white acicular crystals with a strong odor of camphor. In chloroform, acetone, strong alcohol, ether, benzin, and glacial acetic acid, it is freely soluble; in cold water it is soluble to the extent of one per cent., which corresponds in therapeutic value to a four-per-cent. cocaine solution. It is a hypnotic, but that does not limit its applicability. It is an analgesic of value, and very successful as a local anesthetic. For the purposes of this paper I will restrict myself to its hypnotic uses.

How close is its approximation to the theoretical hypnotic will appear distinctly in its formula, as follows:—



It will be observed on inspection of this formula that we have a double supply of the methyl alcohol radicle (CH_3) and a sufficient potency of chlorine (CCl_3). This is at once in conformity with the active constitution of that which I have shown is the theoretical hypnotic.

That being the case I will now pass to the other requisites which I have before mentioned. And here we must call upon the clinical history of the use of this agent.

First, its safety. The customary dose is from 6 to 18 grains, yet we have record of a case in which the patient through misadventure took as many as thirty-six tablets of 3 grains each, in all 108 grains of the substance, and, while cast into a profound sleep for three days, he did not present, either during this sleep or after restoration to consciousness, any symptom to cause the least alarm.

Second, its reliability. In all the use which has been made of this substance, it has never yet failed of prompt action for the purpose for which it was administered.

Third, ease of taking. Chloretone is given in the form of rapidly disintegrating tablets, which are, of course, practically devoid of taste. In crystals it is given either in capsules, which are absolutely tasteless, or even in the uncovered powder, in which the only taste is a not unpleasant flavor of camphor, which is found quite volatile and evanescent.

Combining these statements of constitution and clinical observation, it is shown that in every particular chloretone is our closest approximation to that theoretical hypnotic to which we have been led through a study of the working hypothesis of the sleep-phenomena.

Now, a word in conclusion of this brief paper, a word to indicate after what manner chloretone acts.

The laboratory experiments show us that chloretone, as chloretone, passes unmodified from the digestive tract into the blood, where it may be isolated. The blood conveys the the chloretone to the different organs, and there seems in laboratory experiment sufficient warrant for the belief that it has a selective action on the central nervous system. Here, then, or in some other region of the body, that point not having yet been fully determined, the chloretone is burned down and in the burning down produces its hypnotic effect. That it is really decomposed within the body appears from the fact that, volatile as it is, we do not find it in the expired air; nor has it been positively recognized in the urine.

Now, assuming that chloretone has a selective affinity for the central nervous system, and this assumption seems a very safe one; and still further assuming (and this seems equally safe) that it is there decomposed, we have the theory of its great hypnotic effect. The methyl radicles set free in the burning down are known to retract the dendritic filaments, the chlorine similarly derived to retract the protoplasmic processes. The dendritic filaments under the influence of chloretone lose touch among themselves, the protoplasmic processes are out of contact with the motor cells of the anterior horn of

the spinal cord by the retraction of their end-tufts. The condition which normal fatigue produces has been produced through our safe hypnotic, and sleep follows. The drug has not in itself produced insensibility or even unconsciousness, it has only been used to bring about that cell-retraction which nature demands, and the cell-retraction has produced the refreshment of sleep without distinction as to whether the conditioning circumstance is due to the operation of fatigue or drug.

Two points in the paper to which reference has been made, the regarding of insomnia as a symptom and the making of an ideal hypnotic, have already been the subject of much attention and study by others. The third, the danger from the use of hypnotics, is equally important. Some years ago the profession was not awake to the danger of sulphonal and trional. To-day my suggestions may be now accepted as opinions for the guidance of the physician. That serious and even fatal results may come unexpectedly is shown by the instances in the use of other hypnotics reported by Bampton, Vogel, Schultze, Geill, Pettit, Friedlaender, and others, confirming the importance of the warning which was given at that time.

In brief, then, the advances in the treatment of insomnia have been in the recognition that insomnia is a symptom, in realizing that certain commonly-employed hypnotics may be not only dangerous but even yield fatal results, and, finally, the production of a hypnotic whose chemical constitution rests upon the basis which was suggested in my Montreal paper.

740 Madison Avenue.

PURULENT MENINGITIS: REPORT OF SIX CASES.[1]

By L. NAPOLEON BOSTON, M.D.,
OF PHILADELPHIA;
BACTERIOLOGIST TO THE PHILADELPHIA HOSPITAL AND TO THE AYER CLINICAL LABORATORY OF THE PENNSYLVANIA HOSPITAL; INSTRUCTOR OF OBSTETRICS IN THE MEDICO-CHIRURGICAL COLLEGE.

In the MEDICAL NEWS of May 20, 1899, there appeared an article by the writer, reporting the analysis of the post-mortem records of eighty cases of meningitis. Since that date there have been eleven instances in which autopsy has disclosed the existence of purulent meningitis. Five of these cases were of the epidemic variety; one complicating erysipelas; one purulent otitis media; one following uterine infection; one due to the colon bacillus; one tubercular, and one following traumatism. The following is a report of six of these cases:

Case I.—A middle-aged male was admitted to the hospital in a state of maniacal delirium, resembling that of acute alcoholism. Temperature 101° F., pulse weak and rapid. Died sixteen hours later.

At necropsy the dura mater was found to be normal. The pia mater enveloping both brain and spinal cord was everywhere infiltrated with a purulent exudate of a thick, creamy consistency, lending to these organs a greenish-yellow color. The ventricles were distended with a slightly turbid fluid. Other viscera presented nothing of special interest.

Bacteriology: Two tubes containing bouillon and two of blood serum were inoculated from the meningeal exudate of the brain and cord, and developed pure growth of the diplococcus intracellularis. Two blood serum cultures, where a large amount of the exudate was carried by the inoculating needle into the tube, gave no evidence of growth after forty-eight hours at a temperature of 37° C. Cover-slips smeared with this exudate were found to contain many diplococci, for the most part situated in the polynuclear leucocytes; staining readily by aniline gentian violet, but not by Gram's method.

Case II.—Male, age thirty-eight, was admitted to the hospital with a history of a fall two weeks previously, at which time he received severe contusion of both ankles. He was apparently doing well up to the day of his admission when he had a severe convulsion. On entering the hospital he was unconscious, pulse 120, respirations 30, temperature 99° F., this soon rose to 101° F.; head retracted; eyes turned to the right, suffused and pupils contracted. Over abdomen and legs a petechial eruption was seen. Kernig's sign was not present. Knee-jerks normal. Death occurred five hours later.

Necropsy disclosed nothing of special interest, except purulent meningitis of the brain and spinal cord. Dura mater was normal. Beneath the pia mater was seen a purulent exudate most marked along the course of the vessel and along the fissure of Sylvius. The ventricles contained a normal amount of fluid which was slightly turbid. Cover-slip preparations from pus of meninges showed diplococci, not specially located in the pus-cells. This coccus stained by Gram's method. Staphylococci were also present. The spinal cord presented what appeared to be the result of a meningeal hemorrhage at the upper dorsal region, where a small amount of purulent exudate was seen.

Bacteriology: Cultures made from pus of both brain and spinal cord were found to contain two organisms, the pneumococcus and the staphylococcus pyogenus albus.

Case III.—Female, age forty, was admitted to the hospital in a state of collapse and died a few hours later.

Necropsy: Body of a well-nourished colored woman. At apex of left lung were seen two recent abscesses, the size of a pea. Otherwise the organs of the thoracic cavity were normal. Mesenteric veins were enlarged and had a hard, shot-like feel. Uterine and ovarian veins presented similar conditions and on section were found to be plugged with firmly clotted blood. The splenic and gastric veins were also affected.

[1] Contribution from the Philadelphia Hospital Laboratory, May 20, 1899.

The uterus was enlarged and its endometrium congested and covered by a thick, yellowish pus. Os admitted two fingers readily. Meninges normal over cortex. Beneath the pia mater covering the pons and optic chiasm was seen a seropurulent exudate. The pituary body was surrounded by thick, yellow pus. The vessels entering the orbit were likewise enveloped in purulen exudate.

Bacteriology: Cover-slips smeared with pus from the abscess of the lung, meninges, orbit, and pituitary body showed streptococci; while those prepared from the veins of the abdominal cavity showed streptococci and bacilli. Cultures made from the above sources were found to develop only streptococci, except those made from the abdominal cavity, which contained streptococci and the colon bacillus. Cultures from the uterine cavity showed streptococci and a large motile bacillus (not determined).

Case IV.—An aged woman was admitted to the hospital in an unconscious state; head retracted; tenderness over calf muscles; knee-jerks absent; plantar reflex normal; pupils contracted but reacting to light. Herpes labialis was marked, and a harsh systolic murmur was heard at the apex. Urine contained albumin and granular casts. Temperature ranged from 101° F. to 106° F., the point reached just before death. Pulse 120, weak and compressible. Blood examination showed red cells to be 5,000,000 per cmm., white cells 54,000. Kernig's sign was present a few hours before death, which occurred four days after entering hospital.

Necropsy: Liver presented some fatty change; heart fatty and there was marked sclerosis of mitral leaflets; kidneys showed interstitial changes. Meningeal vessels were prominent and along their course were seen small areas of purulent exudate; between which the meninges were edematous. The cerebellum and pons were covered with purulent exudate, which was reflected over the parietal region on the right. The ventricles were distended with slightly turbid fluid. The pia of the spinal cord was infiltrated at the posterior surface in the dorsal region.

Bacteriology: Cover-slips prepared from meningeal exudate contained diplococci and bacilli. The bacilli and many of the diplococci were decolorized by Gram's iodine solution, while other diplococci were slightly, if at all, affected. Cultures made from meningeal pus gave evidences of a mixed infection. Further study, however, isolated the diplococcus intracellularis, pneumococcus, and the colon bacillus.

Case V.—Female, age twenty-nine, an epileptic, had been in the insane department for five years, where she had been treated for anemia in addition to her mental condition. June 19, 1899, she developed erysipelas of the left foot and ankle, which in a few days spread to the thigh and hip. The usual clinical features of the disease were observed, and two weeks later, when apparently doing well, she died.

Necropsy disclosed what had apparently been a diffuse abscess of ankle. Spleen was enlarged, dark, and firm. Meninges were congested over cortex, while at the base they appeared normal. The ventricles were filled with a yellowish fluid, the choroid plexus were coiled tightly into solid masses, and were covered with pus. Ependyma of the lateral ventricle was smooth, while that of the fourth ventricle was covered with yellow pus. On section the hemispheres presented no gross lesions.

Bacteriology: Cover-slips smeared with pus from ventricles showed streptococci, as did also cultures made on blood serum and bouillon; no cultures were made from the abscess of the ankle.

Case VI.—Female, past middle life, was admitted to the hospital suffering from marked mental depression, answering questions by yes or no, speech drawling. Temperature 99° F., irregular in type, 102° F. being the highest point reached. The friends gave a history of severe headache and pain in the back of the neck for the past week. The head was retracted so firmly as to make it impossible to force the chin forward on the chest. The skin presented a bluish mottling over the shoulders, arms, and right leg. Pupils contracted but reacting to light; heart beats 120 per minute; lungs negative; arms rigid; knee-jerks absent; plantar reflex present. Two days later patient was seen to be in a state of pronounced catalepsy, especially marked in the right arm. Urine contained albumin and many granular casts. Her condition grew gradually worse and she died in coma on the seventh day after entering the hospital.

Necropsy: Liver small and sclerotic; spleen slightly enlarged and soft; kidneys presented some acute inflammatory change. Dura mater was adherent to valvarium. Everywhere the pia mater was edematous, its vessels prominent, and over the convexity was seen a slightly turbid gelatinous material. Reflected over the central portion of the cerebellar hemispheres, as well as over the pons and temporal lobes, there was a thick, cream-like, purulent exudate. Ventricles contained a turbid fluid. Ependyma was smooth, puncta vasculosa well marked. The frontal sinus contained a small thrombosus.

Bacteriology: Cover-slip preparations from meningeal pus contained bacilli which stained readily with aniline-gentian violet, but not by Gram's method; they were not situated in the pus-cells. Cultures, six in all, were made on Löffler's blood serum and glycerin-agar. Two from frontal sinus and three from meningeal pus remained sterile after forty-eight hours at a temperature of 37° C. One serum culture made from fissure of Sylvius presented a profuse growth of the colon bacillus.

The delirium in Case I resembled that of alcoholism, and in one other instance did it assume this form.[1] The fact that two of the cultures presented no growth was probably due to too large an amount of toxins being carried by the inoculating needle into the culture tube. This is

[1] Medical Record, Sept. 2, 1899.

probably why we so often hear that the meningeal exudate may contain many diplococci and yet cultures from this source give negative results, and that the meningococci are often dead or of low vitality. This is not true alone of the diplococcus intracellularis, but of many forms of bacteria, where we, overanxious to secure a growth, defeat our own object by bathing the surface of the culture medium with toxins which are powerful antiseptics. I have found that inoculation from a tube containing bouillon into which some of the purulent exudate has been placed gives good results in certain cases. Case II is of interest since he presented no symptoms of meningitis until twenty-four hours before death. Here the meninges were probably invaded by pyogenic cocci several days after the receipt of the injury. Cases III and V are fair examples of meninges secondary to a streptococcus infection elsewhere in the body. Case IV presented Kernig's sign which, according to Netter, is present in ninety per cent. of all cases where the meninges of the spinal cord are involved. Moderate leucocytosis is an almost constant symptom. Councilman, Mallory, and Wright[1] have seen the white cells reach 31,000 per cm. It is to be regretted that a differential count was not made in this case. The presence of the colon bacillus in the meninges is of no special interest, as the body had been dead twenty-four hours before necropsy; it has been my privilege, however, to study a case where no other bacterium was found.[2] [3] I was not present at the autopsy on the body of Case VI., and do not know by whom the cultures were made. I am, therefore, inclined to regard the presence of the colon bacillus (one culture) as a probable contamination. The bacilli found on cover-slips that were smeared with the meningeal pus, were doubtless the exciting organisms, and possibly gave no evidence of growth in any of the cultures.

THE LEGISLATION NEEDED IN REGARD TO APPARENT DEATH.[4]

BY HENRY J. GARRIGUES, A.M., M.D.,
OF NEW YORK.

I.

ALL laws, rules and regulation governing the treatment of the dead in the city of New York, and I have no doubt the same holds good for the whole State, are only intended to protect the community, and they leave entirely out of consideration the thought that perhaps the person supposed to be dead is not so in reality. Even the very latest Sanitary Code, that of 1898, does not require that the occurrence of death shall be ascertained by a physician.

The blank for a certificate of death at the present date reads:

I hereby certify that I attended deceased from ....19 to ....19 , that I last saw .... alive on the .... day of ....19 , that .... died on the .... day of ....19 , about .... o'clock A.M., or P.M., and that to the best of my knowledge and belief, the cause of .... death was as hereunder written.

Duration of Disease.

Chief Cause .....
Contributing Cause .....
Sanitary Observations ..
Witness my hand this .... day of ....19 .
(Signature),
....., M.D.
Residence,
.....

It will be seen from this that it is left to laymen to decide that death has occurred, and *the physician need not even see the body of the supposed dead person.* All that is required of him is to state from what disease the deceased suffered, how long it lasted, and when he last saw the patient alive.

The Sanitary Code prescribes only that no body shall be buried without a permit (Section 170); that the body shall be buried to the depth of six feet below the surface of the ground and four feet below any closely adjacent street (Section 171); that the undertaker must register name and address (Section 172); that no person shall retain, expose, or allow to be retained or exposed, the dead body of any human being to the peril or prejudice of the life or health of any person (Section 175); and that no person shall allow to be retained unburied the dead body of any human being for a longer time than four days, or, where such death has been caused by a contagious disease, for a longer time than twenty-four hours after death of such person, without a permit from the Sanitary Superintendent or the Assistant Sanitary Superintendents (Section 177). Bodies of persons who have died from a contagious disease shall be disinfected and wrapped in a sheet saturated with a proper disinfecting solution, and placed in a coffin or casket which is to be immediately and permanently sealed (Section 155).

All is in favor of the survivor, not the slightest protection is accorded to the supposed dead. From the moment the householder has declared him to be dead he loses all rights in this world. The physician may sign the certificate of his death without giving a single reason, and without glancing at his body. And when the certificate is signed by the doctor and does not contain any suspicious circumstance the permit for burial is issued by the Board of Health. And still we shall presently see that the question whether a person is dead or alive may be one of the most difficult to decide and requires the nicest physical and physiological tests.

II.

What is Death?—According to the definition

[4] Read before the Society of Medical Jurisprudence.

of the Century Dictionary it is "that state of a being, animal or vegetable, in which there is a total and permanent cessation of all the vital functions." *Total* and *permanent,* here lies the difficulty. Some of the more striking vital functions may be paralyzed, and still the spark of life lie concealed in the body. A person may be in such condition that, if left to himself, the vital functions will be permanently extinct, and still by proper manipulations this same person may be brought back to life. This applies particularly to drowned persons, and perhaps even to electrocuted persons. Since Franklin's time we know that lightning and electricity are one and the same thing; and, since it has been proved that men and animals seemingly killed by lightning occasionally can be brought back to life, the logical inference is that perhaps a similar revival may be possible in a person exposed to a strong electric current.

Death is a gradual process. Even in a case of sudden death one literally dies by inches. Many have probably seen a headless chicken run and fly about in a barn-yard. If one chops off the head of a calf, for several minutes the severed head may be seen to exhibit convulsive movements and show all the signs of difficult breathing. If the tip of a finger be brought close to the eye, the eye will wink, just as does that of a live animal. If the cavity of the chest be opened the heart will be seen to continue to contract and relax for a long time. One may even cut out the heart altogether and place it under a glass shade, and still its regular movements continue, showing that it is not yet dead. This life of the organs is shown still more impressively by opening a large artery in a dog and letting him bleed to death. There comes a point when the dog dies, and would remain dead, if left to himself. But if the severed vessel be tied and blood from another dog is injected, the dead dog returns to life, and may continue living as long and in as perfect health as if he had not been subjected to any experimentation. This is due to the life remaining in the tissues which enables them, under the impulse of fresh blood, to resume all the suspended vital functions. The condition of this bloodless dog offers the greatest resemblance to that of a drowned man, and if it were only more generally known, and people would not take for granted that because a person is drawn cold and limp out of the water he is dead, but would use proper means of reviving him, many so-called drowned human beings might be restored to life, as illustrated by the following example: A young man fell one day into the Seine, at Paris, and disappeared under the surface of the water. Twenty minutes elapsed before the body was found. Pale, cold, limp, motionless, insensible, with thick, blue lips and open staring eyes, was it pulled out. Everybody thought the man was dead, except Dr. Bourgeois, who, amidst the jeering laughter of the mob, began to try to revive the supposed corpse. Several hours passed before the slightest sign of life appeared, and still the intelligent and humane efforts of the physician were in the end crowned with success.

When is a person really dead? Not necessarily when he does not breathe, nor when his heart has stopped beating, nor when he would remain lifeless if nothing were done to revive him, but only when the vital functions have been totally and permanently abolished. The most common causes of apparent death are asphyxia, heart failure, cerebral congestion or apoplexy, exposure to cold, a stroke of lightning, intoxication, anesthetics, and bodily injuries, combined with concussion of the brain..

The first observer who made a scientific investigation of the signs of death was the renowned anatomist, Winslow, a Dane by birth, who became professor at the University of Paris. He had particular reason to be interested in this question, since twice he had been taken for dead and laid out as a corpse. He came to the conclusion that of all signs of death there is only one which is reliable, namely, putrefaction. His contemporary, the great surgeon, Louis, combated his views and wrote a learned work on the certainty of the signs of death. But through a strange irony of fate it was reserved for this same man to publish a case showing that both doctors and nurses may be mistaken in regard to real and apparent death. A woman, who had been confined two days before in the Hotel-Dieu Hospital of Paris, dreading, on account of an epidemic, to stay in the hospital, went on foot to the Salpêtrière Hospital, a considerable distance, where she arrived so exhausted that she fainted. The attendants succeeded in bringing her too, but soon she relapsed and was thought to be dead. The nurses reported to the physicians, that they might remove the corpse. It was left for two hours on a stretcher in the yard, and was then placed in the dissecting-room, where it was left over night. The following morning a young surgeon came to Louis and reported that he, during the night, had heard groans and sobs, but had been afraid to rise. Louis repaired immediately to the dissecting-room, and found the woman dead indeed, but in a position that showed in a most unequivocal way that she had been alive during the night. She had thrown off the shroud, one leg had been stretched from the bier and rested on the floor, and one arm leaned against one of the wooden horses that supported the boards. It was then evident that the poor woman, some time during the night, had awaked from her lethargy, had moaned and sobbed, and tried to rise, until she finally had succumbed to bodily exhaustion and mental anguish, and had become the prey of death. Now she was really dead, before she had only been so apparently.

Since the time of Winslow and Louis the question of apparent death has repeatedly been taken up in France and Italy, countries in which the law prescribes speedy interment, and competent men have been trying to find reliable signs of death before the appearance of dissolution.

III.

Signs of Death.—Among all the signs of death the one that from of old has made the strongest impression on mankind is the cessation of respiration. In all languages we find expressions like these, "to draw the last breath," or "to expire" as synonyms of dying. But people may not breathe and still be alive. In India, monks have the power of entering into a trance during which they have been kept buried for six weeks, and still been revived. New-born children often remain silent for a long time. I have myself worked for two hours and a half with such a child before it began to breathe. Breathing may also be so weak that it is difficult to ascertain. Then a mirror is held before the mouth in order to see the condensed vapor in the breath cloud the surface of the glass. Or a light feather or a flame, is held near to the mouth in the hope of seeing them move. Or a glass brimful with water or quicksilver is placed on the chest in such a way that the slightest movement would cause an overflow. The best of all these tests is, however, the stethoscope or the phonendoscope, instruments by means of which a very faint sound can be heard.

Another sign of death is the arrest of the circulation of the blood. We feel for the pulsation at the wrist, or at the apex of the heart, or, still better, we apply the above-mentioned instruments, by means of which we have a characteristic double sound, caused by the contraction of the heart. A commission appointed in Paris, in 1837, declared the absence during two minutes of any heart sounds to be a certain sign of death, but numerous cases have proved the fallibility of this statement. Of the large number we can only refer to a few.

Dr. Tournier of Paris was, in 1836, called in haste to General Baron von V., a man of eighty, who was supposed to have died suddenly. He found the old man lying on his back with open eyes and mouth. The body was motionless. A mirror held before the mouth was not dimmed. The flame of a match remained unmoved by any breath, nor did it evoke any sign of pain when applied to the nostrils. The dilated pupils did not contract on the approach of a strong light. A careful auscultation did not reveal the slightest respiratory murmur nor any contractions of the heart. Everybody, inclusive of the doctor, held the man for dead, but six hours later he turned over and asked where he was, and he lived two days longer.

The celebrated Parisian physician, Brachet, has published the following case: A man did not feel very well and fainted. The pulse could not be felt, nor were the heart sounds audible, although the stethoscope was applied for three minutes. During the following eight minutes Brachet examined repeatedly the pulse and the heart, without finding the least trace of circulation. In the meantime strong stimulants were applied, and when some ether was poured into the nose, a slight movement of the upper lip was elicited. Twenty minutes elapsed before the heart began to beat, and still the patient recovered entirely.

In another case of apparent death, Andral, also a celebrity of the Faculty of Paris, during six hours could not hear the slightest heart sound.

Besides the tests already mentioned there are others used to ascertain the existence of circulation. If, for instance, a thread be tightened round the finger of a living being the latter will become blue, because the constriction prevents the venous blood from flowing back to the heart, while arterial blood continues to flow in through the deeper vessels. Nothing of the kind takes place after death. But the test is of little value, since it fails in living persons whose heart is too weak to propel the arterial blood into the capillaries of the fingers, as after severe hemorrhage or in cases of advanced consumption. If one pushes a needle into tissues rich in blood-vessels, such as the tongue, the lips, or the cheeks, a drop of blood will escape; not so in the dead; but after a heavy loss of blood none will show in the living either. A similar test on a greater scale is to cup the abdomen. But when in cases of suspended animation the action of the heart is interrupted, there is no blood in the capillaries of the skin, and we do not obtain any, even by cupping.

If ammonia is injected under the skin of a living being a large, dark spot appears; not so in the dead; but there is the same exception to be made as in the preceding test.

After death the arteries become empty, and if we cut one no blood will flow, whereas it will do so in the living. But even this is not quite sure. Thus, Brachet has reported the case of a newborn child, whose body was entirely limp. No pulsation could be felt or heard during several minutes, and no blood flowed from the cut navel cord, and still, by insufflation of air into the lungs the doctor succeeded in reviving the child. After twenty minutes the heart began to beat, and in turn the other vital functions appeared.

The advice has been given to push a long, fine needle into the heart, the slightest movement of which will produce a visible excursion of the outer end. This has been done without harm in animals, but in man it has not been tried, as far as I know.

A valuable sign of death is the purple color assumed by the dependent parts of a dead body. But a similar discoloration has been found in cholera patients before death. It is also found in scurvy, and might be due to contusion.

Another good sign of death is the parchment-like appearance of places denuded of their epidermis, while such places in the living cannot become dry except when a scab has formed over them.

A most excellent sign is the so-called *rigor mortis*, or stiffness of death. Immediately after death the whole body relaxes, but in the course of from ten minutes to seven hours this limpness is replaced by a peculiar stiffness of all the mus-

cles, which can only be overcome by a certain degree of force—and continues for a day or two—until beginning putrefaction, when the former pliability returns.

The only condition which might be mistaken for rigor is that stiffness that is found in persons who are stiff-frozen without being dead, a condition from which people have been recalled to life even at the end of two days. But it is said that a frozen limb on being bent emits a sound like that heard on bending a stick of tin, and which is produced by the crushing of ice crystals.

Only gross ignorance could confound rigor with the stiffness due to tetanus. When rigor is present I take it to be an infallible sign of death, but it may be absent. When a hammer or other object of metal with a suitable handle is dipped in boiling water and then applied to the skin of a living person as a rule it causes the epidermis to be raised in a blister, surrounded by a red circle, while no such reaction, as a rule, takes place in a dead body. But there are exceptions in both directions. In a hydropic person or on a swollen limb the vesicle may be formed even on the dead body, and, on the other hand, it may not appear in very lean and decrepit individuals.

The most irrefutable, and, in the opinion of many, the only absolutely reliable sign of death is putrefaction of a vital organ. In most cases decomposition begins from one to three days after death. A greenish color appears in the groins and extends gradually over the whole body. The corpse emits a disagreeable odor. The tissues become softer. Gases are developed in the interior of the body. The epidermis forms vesicles which burst and expose the denuded skin. The process of disintegration is a slow one, but we need not follow it, since the already mentioned features of it are sufficient proof of real death. These seven tests are simple and of great value.

In another group I have placed other tests which either are less reliable or are more difficult to apply. *Pallor, immobility,* and *insensibility* are, of course, very deceptive. A striking case in point is that of the French cardinal, Monseigneur Donnet, who, when a member of the Senate tried hard to obtain better legislation for the protection of the apparently dead. When a young man he swooned one day while preaching to a large congregation. He was believed to be dead. He could not see, but he could hear distinctly everything; and we can imagine his horror when, unable to move a limb or utter a sound, he heard the tolling of the church-bell proclaim his death. The physician declared he was dead and signed the permit to bury him. The bishop came and, standing at his feet, recited the solemn *de profundis.* The carpenter measured his body for the coffin. But, finally, the voice of a dear friend of his youth made so profound an impression on him that he awoke from his lethargy.

When we hold the hand up against the light, the flesh of the fingers becomes translucent; not so in the dead. But this translucency has been found lacking in people affected with cholera or malaria, or shortly before death; and on the other hand it has been found present two days after death.

Immediately after death the temperature of the body often increases a little, but after that it sinks about one degree per hour, until it becomes like that of the surrounding air; but in cases of apparent death the temperature may also be very low, and after real death it remains occasionally high for days and the cheeks may remain red.

The appearance of the eyes has attracted considerable attention both from laymen and oculists. At the moment of death, the pupil becomes much dilated and remains so for hours. It does not contract at the approach of light, nor does it respond in the usual way to the instillation of eserine or belladonna—the first of which drugs causes contraction, and the second dilatation. Some time after death the cornea becomes dull, the conjunctiva is covered with a thick mucus, the ball softens and sinks back in the orbit. Black spots appear on the sclerotic. Ophthalmoscopic examination shows the vessels of the retina of a uniform pink color, whereas in life the arteries are bright red, and the veins dark brown. Still later the blood-vessels present a rosary-like appearance, due to the presence of air vesicles in their interior. But a renowned oculist has told me that toward the end of life the cornea becomes so dim that one cannot see the retina distinctly. A solution of fluorescine, injected hypodermically, makes the sclerotic green in the living, but does not cause any change in the dead body. The other changes in the eye enumerated above are not reliable or suppose a familiarity with the use of the ophthalmoscope, which even few physicians possess. I have, for instance, seen the white turn black in patients affected with Asiatic cholera, and the dilatation of the pupil may be due to belladonna.

Living muscles contract on the application of an electric current, a contractility which is lost in from one and a half to twenty-seven hours after the death of the individual. Absence of contractility would then prove that the person was dead, but its presence would not prove that he was alive. In fact, it was by observing the contractions in the legs of dead frogs that Galvani first discovered that form of electricity which bears his name. A needle thrust into living tissue becomes rusty much sooner than when inserted into a dead body. Attention has been called to a peculiar buzzing sound which is heard when we apply the ear to the chest or the hand of a living person, and which we also hear in our own body when we insert a finger into the auditory canal. This sound ceases twelve or fourteen hours after death; but in cases of apparent death the vitality is so low that the sound likewise discontinues.

IV.

According to the unanimous testimony of those who have been victims of apparent death but

have been rescued in time from the horrors of live-burial, the sense of hearing remains unimpaired. They could hear every word said while they were in their trance, but it was absolutely impossible for them, in spite of the greatest mental effort to move a limb or in any way to convince the by-standers of their terrible mistake.

Some adversaries of the movement to protect the apparently dead have pretended that even if a person were buried alive there would be no suffering, that he would be smothered almost instantaneously in the coffin, and that all the cases in which coffins had been opened and the bodies found distorted were due to post-mortem changes in the corpse. But this specious plea does not hold good at all, and recently there has been an opportunity to almost experimentally show the sufferings of persons buried alive. In the village of Ternowa, in Southern Russia, there lived a family by the name of Kowalew, who became the center of a little sect, whose members, among other things, refused to give any information to the officials charged with taking a census in 1896. Voluntarily they had themselves walled in by batches in a cave. When, finally, the horrible act was discovered and the graves were opened, it was found that while the very old people and children seemed to have succumbed with comparative ease, the young women displayed fearfully contorted features and stood in postures showing that they actually had tried, in vain, to burst the vault that separated them from the outer world. No, there is no use denying the fact that people apparently dead have suffered the most intense anguish, while preparations were made for their burial, and the most profound despair and physical pain after having been buried alive.

In the city of New York there is not much danger, at least among those who own a few dollars, of being buried alive. The absolutely destitute will probably find their way to a dissecting-room, and the others will be cared for by undertakers, who will place them in an ice-box, and effectually extinguish what spark of life may yet lurk in their inner tissues. Many years ago I treated a beautiful young woman for consumption. When I was called to see her she was already near her end, but imagine my surprise when, one winter morning, during a severe frost, I came and found my patient laid out as a corpse on the floor in a room, all the windows of which had been opened. When I applied the stethoscope to her chest and listened, I could yet distinguish the above-mentioned buzzing sound, although breathing and heart sounds had stopped. I do not doubt that she was dead, but suppose she had only fainted and been in a state of lethargy, to expose her to the low temperature of a northern winter was certainly a sure means of extinguishing the ebbing life. Another case was that of a man, affected with spinal disease. He was paralyzed in both legs and had often intense attacks of dyspnea. During such an attack I was sent for. I was not in, but soon returned, and hastened to the house, which I reached in less than two hours, and still I was late. In the parlor I found the wife bathed in tears and surrounded by sympathizing friends. In the next room I found the undertakers busily engaged in preparing the still warm body for burial. With great difficulty I obtained the opportunity to look for some signs of death. It was half-past ten in the evening. The undertaker and his men were in a hurry to go home or to the saloon, and placed the yet warm body on ice in an almost hermetically-tight box. Such cases are by no means exceptional. Many people have an almost superstitious respect for—or shall we say fear of—the dead. Undertakers display night-bells much more conspicuously than physicians do. A person has scarcely drawn the last breath before the survivors, in the middle of the night, send for an undertaker, who hauls the supposed dead body out of bed, throws it on hard, rough boards, and shuts it up in an ice-box. Nobody even thinks of doubting if he is really dead or not. As soon as one stops breathing, he is surrendered to the tender mercy of the undertaker. And all this in the face of the fact that it is a delicate scientific question to decide whether a person is dead or not.

V.

If it is possible for a competent physician, without waiting for decomposition to set in, to decide whether a person is dead, this is certainly not the case with laymen. It is, therefore, a radical fault in all legislation governing dead bodies that it is left to laymen to decide if death has taken place, that the possibility of apparent death is lost sight of, and that no protection whatever is accorded the supposed dead against ill-treatment, injury, suffering, nay, manslaughter at the hands of the survivors.

First of all the right to decide whether a man is dead or not should not be given to those who happen to be present when he stops breathing, but only to certain individuals, particularly fit by knowledge and training to make the necessary examination. In some European cities there are specially appointed physicians, whose duty it is to view the body and give the certificate of death. Such a system, as all specialization, has the advantage that such physicians would have exceptionally favorable opportunities for studying the signs of death and finding new ones, and that they would acquire exceptional experience in the distinction between true and apparent death. On the other hand, such a system has its drawbacks. The election or appointment to such a position would depend on political affiliation and influence, and physicians who deal much with politics are rarely distinguished for their professional attainments. Secondly, such officials would probably be so overloaded with work that they would be tempted to fulfil their duties in a perfunctory way, which, the writer is informed, is the case in France, where this system is in use in large cities. And, thirdly, they would lack all personal knowledge of the defunct.

In my opinion it might safely be left with the ordinary legally authorized practitioners of medicine to decide if a person is dead, but they ought to be held to perform this duty in a way befitting the enormous responsibility they incur. The certificate of death ought to contain the declaration that they personally have inspected the dead body, and a false statement in this respect should be severely punished. Next, some of the most important and simple signs of death should be enumerated in the blank, and the physician who signs it should be compelled to testify to the presence or absence of every one of them.

I do not know if the rural parts of the State are sufficiently furnished with physicians that such a certificate could be required everywhere. I am, however, inclined to believe it. According to the census of 1890 the State of New York had 5,997,855 inhabitants and 11,139 physicians, that is a physician for every 538 inhabitants; and it would, therefore, seem an easy matter for the physicians to attend to this matter. But if in some places the distance would be so great that the expense of such a certificate would become exorbitant, proper laymen might in such localities be appointed as inspectors of the dead and have the right to fill out and sign the death certificate, but in such cases putrefaction should be the only admissible sign of death.

Furthermore, the law should prescribe that until a certificate of death has been filled out and signed by the proper authority, the supposed dead is to be treated as living, and it should be made a crime to treat him in any way that would cause him pain or do him harm if he were alive. That would put an end to the abominable placing on ice, or hauling the body out of bed and removing it to an ice-cold room, or carrying it into the yard. Until some such law is passed none of us is sure that he will not be buried alive or killed by an undertaker.

Recently Mr. Emile Camis of Paris has, in several scientific societies, exhibited the apparatus invented by the Russian Count Carnice Karnicki, in order to give aid to those who have been prematurely buried. It is very ingenious and simple of construction. A metal tube is inserted in the cover of the coffin, and as soon as the apparently dead revives and moves he raises a large metal ball, sets a bell ringing, fires a shot, and admits air and light into his coffin. As long as we have such delusive protection against live burials, such a contrivance must be welcomed, but think of the horrible situation of a person who awakes six feet under earth and finds himself in a narrow coffin. Much more satisfactory would waiting mortuaries be, where the bodies are kept until decomposition begins. It is true, it is often said, that nobody ever revived in such establishments, but Gaubert[1] says that fourteen cases have occurred in Germany, and he quotes a letter written by Ehrhardt, Mayor of Munich, in which he declares that several persons who were believed to be dead had returned to life in the Waiting Mortuary of that city. But if the apathy of the public in general, and, not least, of the medical profession is too great to introduce such institutions that are expensive and entail a change of habits that would be distasteful to many, let us at least use ordinary precautions in order to avoid the terrible mistake of consigning a living person to his grave.

CLINICAL MEMORANDUM.

LIGATION OF THE FIRST PORTION OF THE RIGHT SUBCLAVIAN FOR ANEURISM OF THE THIRD PORTION.[1]

By A. E. HALSTEAD, M.D.,
OF CHICAGO.

Mrs. F. W., American, aged forty-four years, married; family history, negative; has had three children, the first two being twins. Of these, one died at the age of three months from some unknown cause; the other at six years, from diphtheria. The third child lived two weeks. Has not had any miscarriages nor premature labors. Has had no illnesses excepting the ordinary diseases of childhood, and diphtheria at the age of nineteen. Patient denies having had venereal disease, although she has had treatment for some uterine trouble. The present illness began insidiously about nine months ago without any known cause. She first noticed a feeling of numbness and tingling in the ring and little fingers of the right hand. After about three months she began to have cramp-like pains referred principally to the inner side of the arm and forearm. This was soon followed by shooting and throbbing pains along the posterior surface of the arm and in the right shoulder immediately under the inferior angle of the scapula. These pains at first were paroxysmal in character, but lately have become nearly constant, so that her rest has been broken and her appetite impaired.

Examination shows a fairly well-nourished individual, with a somewhat rapid and irregular pulse. Just above the right clavicle in the subclavian triangle is a tumor, more prominent when the patient is erect than when reclining. This tumor is somewhat smaller than a hen's egg, globular in shape, soft and easily compressible. On palpation a well-marked expansile pulsation synchronous with the systole of the heart can be felt. On auscultation a distinct bruit can be heard. The radial pulse on the right side is perceptibly slower and smaller than on the left.

An operation was performed November 8, 1899, at the Chicago Policlinic Hospital, with the assistance by Drs. J. E. Best, F. S. Coolidge, and P. F. Morf. A curved incision with the convexity downward was made, beginning just above the suprasternal notch and ending externally about two centimeters above the deltoid tubercle of the clavicle, the lowest point being about three

[1] Read at a meeting of the Chicago Medical Society, February 7, 1900.

centimeters below the clavicle. A flap consisting of skin, platysma, and fascia was reflected, fully exposing the subclavian triangle and the origin of the sternomastoid muscle. This muscle, with the sternohyoid and sternothyroid, was divided transversely just above the clavicle, and the internal jugular vein and carotid artery exposed. The carotid artery, and the pneumogastric and recurrent laryngeal nerves were retracted inward while the internal jugular and innominate veins were retracted outward, exposing the lower part of the scalenus anticus muscle. Close to the inner edge of the scalenus anticus, but considerably deeper, the vertebral artery could be located. The thyroid axis was found three-eighths of an inch external to the vertebral. This was traced downward until the subclavian was reached. The sheath of the subclavian was incised for a distance of about one-half of an inch just internal to the point of origin of the vertebral. An attempt was made to pass a ligature about the artery at this point. In doing so the posterior wall of the artery ruptured, giving rise to a profuse hemorrhage which completely obscured the operative field. Several attempts were made to pass the ligature, but as soon as pressure was removed from the artery the hemorrhage recurred. This necessitated the ligature of the artery some distance below the point of rupture, which could not be accomplished without resection of the clavicle. Accordingly, the clavicle was divided about two inches from the sternoclavicular articulation, the sternoclavicular ligaments severed and the clavicle reflected downward. This did not seem to improve materially the situation, so that the inner fragment of the clavicle was removed and with it the upper angle of the sternum. This gave ample room. The artery could now be exposed for a distance of about two inches from the internal border of the scalenus. All of the structures in relation to this portion of the vessel could be easily identified. Three catgut ligatures were quickly placed about the artery and tied, two of these being proximal and one distal to the point of rupture of the artery. This distal ligature had to be placed very close to the vertebral artery. The two ligatures proximal to the point of rupture were placed about three-quarters of an inch apart, and were all tied so as to occlude the vessel, but not to rupture its coats. After the ligatures of the vessel had been completed and the operation-wound sponged dry, the artery could be traced downward and backward for a distance of about three inches from the inner border of the scalenus anticus. In place of there being a common trunk, from which the carotid and subclavian were given off, the latter seemed to pass behind the carotid and come directly from the arch of the aorta. No brachiocephalic trunk could be seen. The relation of the origin of the subclavian to that of the carotid could not be determined. The divided muscles were sutured and the wound closed without drainage. The patient's temperature never rose above 99.5° F.; the pulse, which previous to the operation had ranged from 118 to 130, gradually dropped to normal during the first ten days. The skin-sutures were removed on the fifteenth day, when the wound was found healed by primary union. The patient complained some of the arm and hand feeling cold during the first two weeks. The pain in the arm and hand which was so annoying before the operation has completely disappeared. There is no radial pulse, nor any return of pulsation in the aneurism up to the present time (seven weeks after the operation).

Several points in connection with this case are worthy of consideration:

1. The aneurism involved the entire third portion of the subclavian and encroached slightly upon the second portion, so that the only rational method of treatment was ligation of the first part.

2. The anomalous position of the subclavian vein, which was found above the artery throughout its whole course. Owing to this position of the vein, it was torn while endeavoring to retract it downward so as to reach the artery external to the internal jugular. As a result of this accident a considerable amount of time was consumed before the hemorrhage could be controlled by lateral ligation of the vein.

3. The anomalous origin of the right subclavian and the unusual depth of this vessel were for a time very confusing.

4. The possibility of having to resect the clavicle was considered before the operation. It was determined to ligate the vessel without, if possible. I now considered it a necessary step and strongly recommended preliminary resection of the clavicle and a portion of the sternum in all cases. In my opinion it makes very little difference whether the portion of the clavicle which is resected is restored or not. In the case just reported the patient had an almost perfect clavicle at the end of six weeks, although the inner third together with the upper end of the sternum had been removed.

5. The ligatures employed in this case were of formaldehyde catgut. The suggestion of Souchon of applying two or three non-contiguous absorbable ligatures should be followed in all cases. The ordinary surgeon's knot is all that is required. The ligatures should be drawn sufficiently tight to occlude the vessel, which can be determined by cessation of pulsation in the aneurism, and not tight enough to rupture the arterial wall.

6. Probably the most important factor in securing favorable results in these cases is the preservation of an aseptic condition of the wound.

7. As regards the results thus far obtained in the ligation of the first portion of the right subclavian, this case is, it is believed, the second on record where the patient survived the operation.

Bequest to the Presbyterian Hospital.—Through the generosity of the late Mr. A. G. Cone, the Presbyterian Hospital, Chicago, will shortly receive $135,000.

MEDICAL PROGRESS.

Early Diagnosis of Tuberculosis.—Since it has become the rule to examine the sputum of all doubtful cases many errors in diagnosis are avoided. M. Henkel (*Münch. med. Woch.*, March 27, 1900) points out, however, that frequently no expectoration can be obtained. When the physical examination of the apices is negative in these cases it is important to remember that not infrequently the tuberculous deposits may have their seats in other parts of the lung, such as the lower lobes. The first signs, as a rule, are obtained by auscultation and consist in a dry, creaking sound, often of musical character heard best in the supraspinous or infraspinous fossa or in the intrascapular region. A slight evening rise of temperature is rather suggestive. Finally, where all other means fail, direct aspiration of the lung may be practised and the obtained blood examined for bacilli. If done slowly and carefully this procedure is never attended with danger.

Prognosis of Brain Syphilis.—The phenomena produced by brain syphilis, says C. J. Aldrich (*Cleveland Med. Gaz.*, April, 1900), are so capricious and variable that the general laws of prognosis in acute brain disease hold good in specific lesions to a limited extent only. Youth, alcoholism, and especially excessive venery, induce a peculiar liability to cerebral syphilis. In the young the recuperative powers cause ready response to treatment, but the last two conditions call for a grave prognosis. The underfed, overworked and delicate, living with poor hygienic surroundings, do badly. Females are less liable to acute softening than males. Acute softening and hemorrhage are the same as from any other cause, yet syphilitic apoplexies are seldom rapidly fatal, may recur several times, and may be followed by little, if any, permanent injury. In syphilis of the convexity, or in the localized convulsive seizures of a Jacksonian epilepsy, the prognosis is good. In all cases the lesions of the secondary stage tend to respond readily to treatment, but the tertiary lesions are very resistant. Although the cure is apparently complete, relapses are common, and the cicatricial tissue replacing the lesion may at any time cause pressure by its contraction and result in permanent injury. Lesions often persist because iodide is given in too small doses. It should be administered in rapidly increasing doses up to three drams a day.

Addison's Disease.—L. Huismans (*Münch. med. Woch.*, March 27, 1900) reports several interesting cases of this disease. In the first patient the onset was very insidious, with gastric symptoms. The post-mortem showed extreme atrophy of the suprarenals, a small tuberculous focus in one of the poles of the right organ and a marked contraction of the entire intestinal tract. The second case cited developed a subphrenic abscess which was found to communicate with a large deposit in the left suprarenal, while clinically a remittent fever, meteorism, and general typhoid state set in prior to death. In these two cases no changes were found in the celiac ganglia. In conclusion the author proposes a new theory to explain the symptoms of Addison's disease. He believes that certain toxic substances, such as pyrocatechin, phosphoric and lactic acid, are developed in the intestines and muscles and that these are altered in the suprarenals and there prepared for excretion. When for any reason the suprarenal tissue is destroyed, these substances will remain in the system and lead to a chronic intoxication.

Diagnosis of Pneumonia.—In the *Medical Review* (March 31, 1900) L. H. Behrens has reported two cases which proved to be lobar pneumonia, but which were very difficult to diagnosticate at the beginning on account of the peculiar and limited symptoms presented. In one the attack began suddenly, with paroxysms of sharp, lancinating pain over the precordium, extending to the left shoulder and down to the left arm. Physical examination was negative and the pains gradually ceased, to be followed in about three hours by another severe paroxysm similar to the first but with considerable pain in the epigastrium also. The temperature was practically normal for about fifteen hours, and a few moist râles at the end of twenty-six hours were the only physical signs present. Evidences of consolidation appeared in about forty-eight hours. In another case the onset of the disease closely simulated the excruciating pains accompanying the passage of a renal calculus, the pain centering over the kidneys and extending to the umbilicus, especially on the left side. This was followed in a few hours by pain in the epigastrium and vomiting, and, as the patient had been very alcoholic, the diagnosis of gastritis was made. Thirty-two hours after the onset a few crepitant râles could be discerned, but the temperature was still normal. The temperature remained low throughout; the delirium was marked, probably due to alcoholism, and the recovery very slow.

Alcoholism.—After a prolonged trial of the Keeley cure, the injection of strychnine nitrate, the use of methylol and of quinine and nitromuriatic acid, the Cery retreat for inebriates has adopted a treatment described by C. de Martines (*Revue méd. de la Suisse Rom.*, March 20, 1900). Almost always the patient during the first few days becomes violently agitated, throws things about and attempts to hurt himself and others, so, as restraint has a bad effect, he is allowed free movement in a room with padded walls and devoid of furniture. Two glasses of wine a day are allowed during the first week or two, but no longer. As soon as the mental excitement subsides, the patient is made to walk in fresh air until tired, and takes a warm bath for half to one hour each day. The only drugs used are chloral hydrate, twenty to thirty grains, to produce sleep, preferably given in a little wine or beer, or, if

this is refused, one-sixtieth of a grain of duboisine or hyoscine hypodermatically. Morphine is never employed as it is considered responsible for many untoward effects in the treatment of these cases. The bowels are regulated by artificial Carlsbad salt or other saline purgative. The lungs are examined every morning as at any time a pneumonia may develop. Any medication is more rapidly absorbed if it is given in a slightly alcoholic mixture.

Blood-Test for Syphilis.—Since the report of this test by Justus, an assistant in Schwimmer's clinic at Budapest, very little confirmatory work has been done except by Drs. Cabot and Mertins of Boston. Recently D. H. Jones (*N. Y. Med. Jour.*, April 7, 1900) has applied the test to fifty-three cases drawn from the service at Gouverneur and Bellevue Hospitals. The test depends on the asserted fact that a single inunction of mercury in all untreated cases of secondary, tertiary and congenital forms of syphilis causes a reduction in the hemoglobin, due to the sensitiveness of the red blood-corpuscles to the action of the drug, while in non-syphilitics, no reaction occurs. Of seventeen active syphilitics, thirteen responded and four were negative. One active case under treatment and two latent cases were also negative. Out of fifteen cases of chancre, only three responded, and all the control cases, eighteen in number, were negative. The result shows that the test is liable to fail in two classes of cases in which a diagnosis is especially desired, *viz.*, in latent cases and in early chancre and sometimes at the beginning of the secondary stage. The range of usefulness has not yet been worked out, however, and it is very likely that it may be a very valuable method of corroborating a diagnosis.

Chronic Carbon Monoxide Poisoning.—The acute cases of poisoning by carbon monoxide gas are numerous and usually easily recognizable. When the poison is slowly absorbed by the system for a considerable length of time, a chain of symptoms is liable to develop which does not by any means point clearly to the source of the trouble. T. J. Yarrow (*N. Y. Med. Jour.*, April 7, 1900) has seen a well-marked case of the above chronic condition and gives some valuable information in regard to the diagnosis of this malady. The symptoms, although sometimes vague, may be summed up as anemia, generally of a simple type, with or without leucocytosis, frontal headache, anorexia, tinnitus aurium, vertigo, foul taste in the mouth, abdominal pains, often of a colicky character, persistent disorder of digestion, and general lassitude. The carbon monoxide forms a very stable compound with the hemoglobin, interfering greatly with its oxygen-carrying power and giving a cherry-red color to the blood. This causes the florid countenance in acute cases but not the more chronic ones. Examination of the blood by the spectroscope is the only certain method of making the diagnosis, and consists in the dilution of a small quantity of blood with distilled water, followed by a direct examination of the fluid by the hand spectroscope or the microspectroscope. The absorption bands are noted and ammonium sulphide or Stokes reagent is then added, the mixture thoroughly stirred and slightly warmed. If carbon monoxide be present it will be found that the normal reduction to hemoglobin does not take place, but the absorption bands persist and are somewhat nearer the violet end than those of oxyhemoglobin. Several chemical tests may also be made. A small leak from the artificial gas-pipes is probably the most common cause of this condition, and in the crowded, poorly-ventilated tenements it is, no doubt, more often present than is supposed.

Whooping-Cough.—In the grave cases of pertussis, accompanied by frequent and severe vomiting, with consequent loss of flesh and strength, dependent upon prolonged spasm of the glottis, N. R. Norton (*Archives of Pediatrics*, April, 1900) advocates intubation. The paroxysm begins as usual with excitement, a desire for support, the spasmodic cough and even cyanosis, but when the inspiratory effort is made there can be no glottic spasm and the paroxysm terminates abruptly without the least distress or vomiting. Hard rubber intubation-tubes are preferable to metal ones as spicules of calcareous matter deposit upon the latter and cause excoriations and ulcerations. As general treatment for whooping-cough the author administers carbonic-acid gas by rectum. The gas is generated slowly by adding one-half ounce of tartaric acid in crystals to a solution of six drams of bicarbonate of sodium, and it is run into the rectum for about five minutes through a rectal tube three times a day. During the administration the skin is flushed and a mild diarrhea may be induced, but the severity and number of the paroxysms is reduced, and the vomiting ceases.

Kernig's Sign in Infants.—Although considering Kernig's sign of meningitis a valuable diagnostic aid in adults and older children, F. A. Packard (*Archives of Pediatrics*, April, 1900) warns against attaching too much importance to it in the infant. Two cases at sixteen months and one at four months, proven by autopsy to have had meningitis, failed to give the sign. One case at four months responded well to the test and autopsy showed no anatomical change in the meninges.

Uses of Creosote.—Tubercular inflammations of the lung are probably the common lesions in which creosote is employed and yet its usefulness is, no doubt, considerable in many other conditions. T. C. Test (*N. Y. Med. Jour.*, April 7, 1900) has reported some of his clinical observations on the action of this drug in other affections. Several cases of very obstinate intestinal fermentation, flatulence, and autointoxication, are cited, which were treated by ordinary digestive ferments and intestinal antiseptics without any material

benefit. Creosote, in doses of about one minim three or four times per day, well mixed with a preparation of malt, gave surprisingly good results. It is not known whether the action of this drug is a direct one on intestinal contents or an indirect one, as a glandular stimulant during elimination, but in such small doses the indirect action must be very slight. Several cases of whooping-cough were markedly improved by creosote and as an antemetic it sometimes proves very efficacious on account of its sedative action on mucous membranes.

Gouty Deposits.—So many physicians have been baffled in their attempts to cause the absorption of gouty deposits that new suggestions are always welcome. Believing that the local application of a solvent would be most beneficial E. L. H. McGinnis (*N. Y. Med. Jour.,* April 7, 1900) has used a solution of iodide of lithium applied to affected parts by means of absorbent cotton. The positive pole of a galvanic battery was then closely applied to the wetted cotton and a current of from ten to fifteen milliampères was used for from eight to ten minutes. This treatment was employed daily and within a very short time a marked diminution in the deposits resulted in the three cases reported by the author.

Analysis of Gastric Contents.—A new method of easily determining the amount of combined hydrochloric acid in the gastric juice is proposed by O. Cohnheim and H. Krieger (*Münch. med. Woch.,* March 20, 1900). The entire acidity is determined in 10 c.c. of the filtered fluid by the usual methods. A similar amount is then measured off and phosphotungstate of lime added. This has the property of reacting with acid albumin with the production of free hydrochloric acid and phosphotungstate of albumin which falls as a precipitate. On filtering, the hydrochloric acid can easily be determined, when, on deducing the result from the entire acidity, the amount of combined acid can readily be estimated.

Treatment of Whooping-Cough.—Chas. G. Kerley (*Archives of Pediatrics,* April, 1900) reports a study of various methods of treatment tested in 752 cases of pertussis. No treatment was used until the height of the paroxysmal stage had been reached, usually ten to fourteen days. The age was from six weeks to twenty-six years, half being less than two years. The attacks lasted from three to twenty weeks. The very young and the very delicate often did not whoop during severe attacks. Convulsions and hemorrhages from the nose, eyes and ears, or beneath the skin, were observed. No benefit was obtained from insufflations of resorcin and boric acid with bicarbonate of sodium; from inhalations of vapocresoline, or from alum, horse-chestnut leaves, or dilute nitric acid. Bromoform was of service in only three out of twenty-two cases; cocaine hydrochlorate, one-tenth grain every four hours for a two-year-old child, was of limited value. Quinine, twelve to twenty grains in twenty-four hours, was very efficacious, but tended to derange the stomach and produce vomiting, and was difficult to administer to young children on account of its bitter taste. Belladonna was tried in sixty cases and was pushed to its physiological limit without influencing a single case in the slightest degree. The bromides were of much value, and antipyrine was found to be the best of all the drugs employed. These last two drugs are well borne if given in tablet form or in syrup of raspberry on a full stomach, and, when given together, more effectively control the disease than either alone. The dose for a child of eight months is one-half grain of antipyrine and two grains of sodium bromide every two hours. A valuable addition to the drug treatment in the very young, or those with complicating bronchitis or bronchopneumonia, is the steam spray for fifteen minutes every two hours. Steam inhalations medicated with creosote, turpentine, or wine of ipecac, may be of some value. In every case abundance of fresh air is a requisite.

Preventive Operation in Appendicitis.—M. Moullin (*Edinburgh Med. Jour.,* April, 1900) says that every case of inflammation of the appendix even if it is catarrhal at first, becomes infective before many hours. The epithelium, which is the protecting barrier, is soon injured, and then the ever-present bacteria invade the wall. In even the mildest cases, microscopical examination shows the organisms in the lymphatics. At the onset of appendicitis, it is impossible to say what is to follow, gangrene, ulceration, perforation, septic lymphangitis, portal pyemia, or circumscribed abscess. In some of these cases preventive operation offers the only hope. In others operation must come at last. It, therefore, would seem perfectly fair to make an exploratory incision in the right iliac fossa and treat the appendix according to findings, very early in the attack, *i. e.,* before the onset of gangrene or suppuration would be apt to occur. If all the cases, which, under the present methods, finally come to operation, were operated upon before thirty-six hours have elapsed, some lives, which are now lost, would be saved, and there is no reason to think that any of them saved under prevailing methods would be exposed to additional risk. Some cases may never require operation. In the great majority of cases it is possible, by the end of thirty-six hours, to form a fairly accurate judgment of their gravity. The key is to be found not so much in the intensity of symptoms, as in the way they advance or recede. If the symptoms begin mildly and increase, or if they begin with severity and do not improve in thirty-six hours, or if sudden exacerbation occurs, suppuration is imminent. Increasing rapidity of pulse is invariable in grave cases, but the absence of one or more of the other so-called cardinal symptoms is of no importance. Operation must be preventive in the narrow sense of the term. Gangrene may occur in twenty-four hours, suppuration often in forty-eight.

Each case must be operated upon according to its merits. In many cases operated upon on the fourth or fifth day (so-called early operations) the abdomen is distended and the intestine paralyzed. These cases, which run up the mortality, are the ones which could be saved by a timely exploratory preventive operation.

Sterilizing the Hands and the Patient's Skin.—The tincture of green soap, according to Honel *(Beit. z. klin. Chir.,* vol. 26, p. 475), is an easy and sure method of sterilizing the hands before an operation. The hands should be thoroughly scrubbed with it for five minutes and then wiped, but not washed with water. If they remain slippery, they may be quickly rinsed in a solution of bichloride of mercury 1-1000. The skin of the patient may also be prepared in the same manner. Honel has tested this method in about two hundred cases and has found it satisfactory.

Sealing of Aseptic Wound.—H. O. Marcy *(Annals of Surgery,* April, 1900) believes that clean-cut operative dissection is a very important step toward obtaining primary union. For germs to grow it is necessary to have a favorable soil and this is produced by tearing, bungling, blunt dissection, clamping of much tisue, and tying of many ligatures. Therefore, not only should the operative field, the surgeon's hands and the instruments be rendered aseptic, but, at the end of operation, the tissues left in the patient should be as little damaged as possible. Like tissues should be closely apposed by buried, absorbable sutures, preferably of tendon soaked in 1-1000 bichloride, and finally the skin wound closed by an absorbable subcuticular suture. (Catgut and silk are discarded because their twisted surfaces give many crevices for the lodgment of infectious material.) Such perfect apposition, with physiological rest, gives rapid primary union, and very little serum exudes. Therefore, the heavy bungling dressings in common use should be dispensed with and iodoform collodion used. There is nothing to come out, and the collodion allows nothing to enter.

Conservative Operation on Fibroids.—W. L. Burrage *(Bost. Med. Surg. Jour.,* April 5, 1900) states his belief that all operations on the uterus and its adnexa should be strictly conservative. During menstrual life the uterus should be removed only when it is the seat of ineradicable disease, and fibroids should not be so classed except when they cause excessive distortion, or are so extensive that their removal would obliterate the uterine cavity. In women near or past the menopause, hysterectomy is preferable to myomectomy, especially when the cervix is much diseased. In cases of small submucous tumors, the cervical canal should be slowly dilated during the twenty-four hours preceding operation. The tumor is removed by twisting, snaring or morcellation. With a subperitoneal or subvaginal tumor in the cervical region, enucleation may be accomplished through an anterior or posterior colpotomy without opening the peritoneum. With other subperitoneal tumors laparotomy is necessary. The tumor is removed through a lateral incision in its capsule, and the wound closed by a continuous catgut suture. Electricity relieves pain and hemorrhage, but exerts no lasting effect on the tumor. Removal of the adnexa often fails to relieve. Ligature of the uterine arteries often fails because of the free collateral circulation. The adnexa are often diseased in fibroid cases. They can be appropriately treated at the time of a myomectomy. When necessary hemorrhage may be controlled by an elastic ligature about the cervix. Myomectomy requires more skill and longer time for its successful performance than does hysterectomy, a fact not to be lost sight of in operating on weak and exsanguinated patients.

Diazo-Reaction in Phthisis.—The diagnostic and prognostic value of Ehrlich's diazo-reaction when applied to cases of tuberculosis is made the basis of an interesting article by M. Michaelis in the *Berliner klinische Wochenschrift* (March 26, 1900). In the first place he divides all diseases into four groups with reference to their susceptibility to the diazo-test. These four groups are: (1) Those in which the diazo-reaction practically never occurs, *viz.,* spinal diseases; chronic organic affections, such as nephritis, endocarditis, malignant tumors, etc. When the reaction does take place in these diseases it is due to some secondary bacterial process, such as ulceration of a carcinoma, decubitus in spinal diseases, and so on. (2) This group of diseases is characterized by a positive diazo-reaction, such as typhus abdominalis, measles. (3) This group only rarely reacts to the diazo-test and when this is positive it prognosticates severe types of disease and complications. Pneumonia and diphtheria furnish us with examples. (4) The last group embraces all the tuberculous processes. Here the diazo-reaction is of special importance, both as to diagnosis and prognosis. When in patients without temperature we get continuous diazo-reactions, we may be almost certain that we are dealing with tuberculosis. As a means of differentiation between ascites due to cirrhosis or tuberculous peritonitis this is invaluable. Occasionally, however, peritoneal carcinoma reacts also to the test. Positive reaction in meningitis likewise points to a tuberculous origin of the affection. In miliary tuberculosis the test never fails. In pericarditis and serous pleurisy the reaction differentiates between the rheumatic and the tuberculous origin. It is chiefly in pulmonary tuberculosis, however, that the reaction is of high prognostic value. Those cases of phthisis which give absolute, undisguised, positive reactions to the diazo-test are to be considered fatal as to prognosis. The reagent used by Michaelis is the original one of Ehrlich:

Acid sulfanilic 2,5 ..... } ..Reagent A.
Acid muriatici 25 :500.. }
Natrii nitrosi 0,5 :100 .....Reagent B.

Of Reagent A., 49 c.c. are taken together with

1 ccm. of B. and well shaken. Then to about 10 c.c. of urine is added a like quantity of the reagent and again the mixture is well shaken. Finally, about one-eighth of the quantity of ammonia is added. Then, with positive results, a red coloration of the foam takes places. If the urine be allowed to stand for twenty-four hours a dark green precipitate will form. It is to be noted that the ammonia is to be added, not by drops, but the requisite quantity at once. The previous ingestion of certain drugs such as naphthalin, chysarobin, gallic acid, tannigen and tannalbin seems to prevent the reaction from taking place. The presence of a positive reaction is independent of fever, of the number of tubercle bacilli and of the quantity of the sputum. The diazo-test is rarely positive in mild cases of tuberculosis; and only when acute infections set in, which of themselves alone would give negative results, does the diazo-test give a positive reaction. Thus may we, in a seemingly benign influenza, pneumonia or pleurisy, be enabled to foresee a succeeding phthisis by means of a positive Ehrlich test. In those cases of phthisis with positive diazo-reaction, Michaelis has been able to prognosticate a fatal issue in the majority of cases within six months. In 167 heretofore observed cases of phthisis the following results have been drawn by him:

Negative diazo-reaction, cured 5, improved 44, unimproved 5, died 3; positive diazo-reaction, 15 improved, 16 unimproved and 80 died.

These statistics speak for themselves. Clemens also has shown that out of 100 of his cases of phthisis with fatal termination 87 gave continuous positive reactions with this test.

Operative Treatment of Spasmodic Torticollis.—From a review of the literature as well as a personal experience with 95 cases of spasmodic torticollis, E. Kalnius *(Beit. z. klin. Chir.*, vol. 26, page 189) gives the following conclusions. The spasm may be tonic or clonic. The muscles are involved in coördinated groups rather than singly. In their order of frequency they are, the sternomastoid, the trapezius, the splenius and the digastric. The deeper muscles of the neck, the posterior recti, major and minor, and the superior and inferior obliques, are less often involved. The four chief causes of the trouble are a nervous disposition, overuse of the muscles in occupation, cold and trauma. The prognosis is rather unfavorable except in hysterical and very recent cases. Sometimes the disease after progressing to a certain degree remains stationary, and sometimes it progresses until death results from exhaustion. Medicine is of little value except in hysterical cases; electricity better deserves a trial. Galvanism should be used on the affected side, and faradism on the sound side. The anode should be placed on the affected muscle. Other methods of treatment are massage, orthopedic apparatus and operation. Operation should always be followed by gymnastic exercises and suitable apparatus. The various operative efforts suggested are stretching, or division and ligature, or resection of the spinal accessory nerve; or resection of the cervical sympathetic; or of both of these nerves; or division of the various muscles affected. Perhaps the best results have been obtained by resection of the nerves of the affected muscles, although in certain cases it is better to resect both muscles and nerves.

Diphtheria Antitoxin.—Statistics of a large number of cases of diphtheria treated with antitoxin show beyond doubt that the mortality of the disease is greatly decreased by the use of antitoxin. Some writers advise as the initial dose of antitoxin in young children 1000 immunizing units, to be repeated every twenty-four hours if the symptoms are aggravated or stationary. In severe cases these same writers give from 1500 to 3000 units, as initial dose, and repeat it in twelve hours if the symptoms do not yield. Others give children under two years an initial dose of 1000 i. u., and those over that age from 1500 to 2000 i. u., to be repeated in from eighteen to twenty-four hours, with a third dose if necessary. Baginsky gives children under two years an initial dose of 600 i. u., if the case is mild, and 1000 i. u., if the case is severe. To children over two years old he gives in mild cases an initial dose of 1000 i. u. and in severe cases as high as 3000 i. u. He gives a second dose of from 600 to 1000 i. u. within twenty-four hours in any of the cases if necessary. The English authorities recommend an initial dose of from 6000 to 20,000 i. u. and not infrequently an initial dose of 50,000 units is given. The size of the English doses arouses a suspicion that the standard strength of the serum is low or that its strength is estimated differently than in other countries. J. H. Musser *(University Med. Mag.*, March, 1900) has used much smaller doses than any of those and demonstrates his method and the size of the doses he uses in thirteen cases which he reports. His method has been to give children under eight years of age an initial dose of 500 immunizing units, to be repeated at intervals of six hours if the fever does not fall, if the strength of the patient does not improve, or if the local manifestations are spreading. To children over eight years of age he gives 1000 i. u. as an initial dose, and repeats it at intervals of eight to twelve hours if necessary. In all of the writer's cases except one there was a critical fall of the temperature within a few hours after the initial dose of serum. In four cases the temperature fell to normal, and in the others the fall was at least 2° F. There is usually a transient rise of temperature after an injection of serum, but it does not last long, is without meaning and is followed by a fall to normal. In all the cases the serum slowed and strengthened the rapid weak pulse which was present. The strengthening influence of the antitoxin on the heart is especially shown in the case of a little girl who had most remarkable evidences of stenosis of the mitral and aortic valves, and in whom compensation had never been fully

established. She passed through an attack of diphtheria with no signs of undue cardiac weakness. The membrane began to loosen in each case soon after the first injection of serum. Five of the cases the writer considered seriously ill, and their recovery due solely to the antitoxin. The initial dose in one case was 2000 and in three cases 1000 units, but in all the other cases it was below 800 units, in most of them 500 units. The subsequent doses varied from 200 to 1000 units. These small doses were followed by prompt and satisfactory results. Musser says this method implies recognition of the disease at the earliest moment possible and very close observation. He has not lost a case under this method, and the results obtained from the small doses seem to be as good as any reported.

Contagiousness of Erysipelas.—W. Respinger *(Beit. z. klin. Chir.,* vol. 26, p. 261) says that the actual extension of erysipelas from one patient to another can usually be traced. Epidemics of the disease disappeared with the dawn of antiseptic surgery. Idiopathic erysipelas is an obsolete term; and the idea of contagion through germs floating in the air is not supported by careful hospital experiments. These show that the streptococci of the disease are conveyed only in the purulent discharges. The scales of loose epidermis, or epidermis cut from an affected area, the sweat, and even the contents of blebs, as long as they were not purulent, were found to be free from streptococci. The conclusion is that infection proceeds from the discharge of erysipelatous wounds, and that these should be treated as other infected wounds, but that the patient should not be handled as though he were suffering from a contagious disease.

Anthrax.—Anthrax being a rare disease in this country, a case reported by Fred. D. Bird *(Intercolonial Med. Jour. of Australasia.* Feb. 20, 1900) is of interest. The patient, a man twenty-four years of age, a slaughter-man by trade, noticed that in one cow which he killed, the spleen was swollen and engorged with dark blood and that on cutting her throat there was much less bleeding than usual. The cow had slight epistaxis, but no blood-stained discharge from either rectum or vagina. The patient had seen these conditions in undoubted cases of anthrax. For four days the patient noticed nothing. On the fourth day he cleaned the trough into which the blood from this cow had drained. The man was positive that at this time he had absolutely no scratch, or cut, or lesion on his hands or forearms. Eight hours later he noticed a small red pimple, not painful, just above the right wrist in front. The next day this pimple had become a large painful bleb with a darkish center. At this time there was no swelling of the forearm and the man did not feel ill. In the evening the patient was very ill, temperature 101° F., pulse 100, face flushed, skin hot and dry, tongue moist and coated, and he had a persistent headache. There was no vomiting. The forearm and arm were tense with much swelling. The vesicle, at the point of inoculation, was about the size of a florin and was surrounded by much redness. The center of the vesicle was dark yellowish-gray, but it contained almost clear fluid. The joints of the arm were not affected. A severe lymphangitis extended along the inner and front aspects of the arm up to the axillary glands, which were very much enlarged and painful. The swollen axillary glands, and the lesion at the point of inoculation were entirely removed, and numerous deep incisions made in the arm and forearm. Pure carbolic was applied to the site of the initial lesion and the whole limb was invested in a large carbolic foment. The patient improved at once and at the end of a week was well. The rapidity of the onset of all the symptoms, and the marked absence of pain is especially to be noted. The diagnosis was confirmed by the microscope and cultures.

Operations on Glycosurics.—A. L. Fisk *(Annals of Surgery,* April, 1900) says the opinion is growing that, while glycosurics are not good surgical subjects, yet, with careful selection of cases and perfect asepsis, operative procedures are safe. Of course, in acute surgical diseases as appendicitis, strangulated hernia, etc., one must disregard the presence of sugar, although it adds greatly to the gravity of the prognosis. Sugar is very common in appreciable amounts as the result of toxic and traumatic lesions, and there is no reason to suppose that operations on such lesions are rendered more severe. The previously-diabetic are liable to various complications, therefore careful inquiry must be made into the past history, before allowing the prognosis to be biased by the mere presence of sugar in the urine. While, therefore, the presence of sugar in the urine is not an absolute contraindication to operation, it necessitates great care in the selection of cases, in the determination of the kind and extent of operation, and the strictest asepsis. Infection occurs from without and always as the result of error in technic. When infection does not occur wounds heal kindly but slowly, especially granulating wounds. The vascularity of tissues must be interfered with as little as possible. In gangrene of the extremities it is better not to use the Esmarch bandage in amputating, as it damages the vitality of the vessels.

Asthma in Neurasthenics.—In neurasthenics, nervous dyspeptics, suffering from habitual constipation, and feeling weak in spite of a good appetite and an appearance of being well nourished, the intensity and frequency of asthmatic attacks can be notably diminished and the general nervous condition improved by the administration of belladonna and nitrate of silver. For instance:

℞ Argenti nitrat.....gr. ii
Ext. belladonnæ.....gr. ii—v
Ext. gentianæ.....3 ss.

M. Ft. pil. No. XXX. Sig. One pill three times a day after meals.—*Golonbow.*

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 Fifth Avenue, New York.

Subscription Price, including postage in U. S. and Canada.

SATURDAY, APRIL 14, 1900.

RHEUMATISM AS A DIAGNOSTIC SCAPEGOAT.

Rheumatism is a most convenient word. Like charity it covers a multitude of shortcomings, diagnostic as well as pathologic. It is easy to nod one's head, look wise and pronounce a painful affection rheumatism, and it is not difficult to outline a course of antirheumatic treatment. As the ordinarily prescribed antirheumatics are the coal-tar antipyretics and analgesics, which, in peripheral nerves, ameliorate painful conditions of the most varied kind, alleviation of pain almost invariably follows. A toothache may be greatly benefited by the same remedies, yet it will scarcely for that reason be considered rheumatic in origin. The therapeutic test for rheumatism, since we have no specific treatment for the condition is, of course, unreliable. Many of the painful conditions, both subacute and chronic, which are diagnosticated and treated as rheumatism are really manifestations of other pathologic conditions, and any rational therapy must be founded on more accurate diagnosis.

Some times the mistake of diagnosis has no serious consequences. The chronic condition underlying the painful affection is not rendered worse by the neglect to treat it directly. Not infrequently, however, delay is fraught with unfortunate results. When an incipient tuberculosis of the ankle or knee-joint is treated by rubbing and passive motion instead of by rest, when the referred pains of tuberculous hip-joint disease are misconstrued as rheumatic, harm always results. Fortunately, the subject has been so thoroughly impressed upon the practitioner by the appeals of the orthopedic surgeons that the condition of tuberculous joints is not often mistaken in our day.

The most fruitful sources of error now are undoubtedly flat- or weak-foot and the various occupation neuroses in the hand and arm. The tendency of weak-foot to cause a painful condition which is felt near the base of the big toe and around the heel, as well as in the ankle-joint, marks it out because of its diffuseness as almost surely rheumatic in origin. Usually the calf-muscles suffer in their function because of the spasm around the ankle and the loss of mechanical advantage by the alteration of the arch of the foot. This causes pain in the leg as high as the knee and confirms in the careless observer the diagnosis of rheumatism. Needless to say, no amount of antirheumatic treatment will relieve the symptoms.

Writers' cramp is but one of a series of spastic and painful conditions that may develop from improper use of arm-muscles. Pain in the muscles attached to the epicondyle has been noted from carrying an umbrella on a blustering day. The painful "skirt-wrist" from holding up heavy skirts is a familiar example in these days. Various neurotic conditions of the arm for which there is no localized anatomical basis have been classed frankly as brachyalgias. All of these conditions are liable to exacerbations in damp weather, somewhat as dental nerves that have once been affected are more sensitive while dampness prevails.

Most of these conditions require a tonic rather than the depressant antirheumatics. Most of them are benefited by local measures. Weak-foot requires the special orthopedic treatment suited to the condition. The pain due to the improper use of arm-muscles can only be overcome by the correction of bad habits in their employment. In a word, definite diagnosis of the exact parts affected by the painful condition is absolutely necessary, not only to discover the true character of the affection that is complained of, but also to assure the rational therapy of the condition.

NO EXPECTORATION, NO TUBERCULOSIS.

The Municipal Council of Paris has recently passed an ordinance prohibiting expectoration upon the sidewalks and streets of that city and imposing appropriate fines and imprisonment. The *British Medical Journal* in commenting upon this and urging the London County Council to take similar action enforces its argument by the statement that "In many of the principal cities of the United States spitting upon the sidewalks or pavements is forbidden and the prohibition is rigidly enforced."

This to us is a most pleasing bit of intelligence or rather it would be, were we permitted to lay this flattering unction to our souls. But candor compels us to admit that our English cousin has, we fear, taken the will for the deed and rather overstated the actual situation. 'Tis true that such laws are upon our statute books but, alas, in shame be it confessed, their observance consists more in the breach than in the doing. We have not been wanting in convincing orators who have depicted the dangers of the dissemination of tuberculosis by means of the sputum in such glowing colors as to crystallize conviction into statutes and ordinances, but the hygienic sense of the people has not yet become sufficiently enlightened to uphold their enforcement. Indeed the scenes that are constantly witnessed upon the streets of New York are enough to bow the head of every intelligent citizen in shame and humiliation. Upon a breezy morning recently a policeman sought protection from the chilling blasts in one of the receding angles of the Dewey Arch and, as if to hedge himself about from all intrusion, with his back to the corner, he erected upon the pavement a geometrically constructed barricade of expectoration, reaching in a circle from one protruding angle of the base of the Arch to the other. The process was sufficiently disgusting in itself, but when to the sight of it was added the reflection that the perpetrator was an officer charged with the enforcement of the very law he was so complacently violating, the hopelessness of the situation became oppressive. But the sequel was if possible still more disgusting. Toward evening of the same day, after the sputum had been dried to a powder in the sun and air, a woman, in the guise of a fashionably dressed lady, with her arm twisted around in the present characteristic fashion so that she might raise her skirts from the ground, was standing, waiting for a trolley car, directly over the spot beautified in the morning by the geometrically arranged sputum. The car passes a little beyond its expected stopping-place, and the lady in her eagerness to get on board lets go her grip upon her skirts and makes a run for the car. A more perfect sweeping the pavement could not have had. The dust rolls up in masses beneath those skirts and finally bursts out at the sides in such clouds that the passer-by, who had observed the performance of the morning, held his breath in self-protection and waited for the dust to subside. The woman carried the most of it away, however, in the meshes of her dress and skirts, to be shaken out and disseminated about the rooms of her home. There is undoubtedly no more fruitful source of tuberculosis infection than in the process above described—a procedure transpiring daily, yes, hourly, upon the streets of thousands of cities all over the civilized (?) world. And yet we wonder that tuberculosis is so prevalent, that it seeks its victim in such unexpected places and causes one-seventh of all the deaths that claim mankind.

THE PATHOLOGICAL INSTITUTE.

The New York State Legislature has adjourned. During the final days of the session legislation was enacted with such startling rapidity that it requires no little time to take observations and see where we are. In the appropriation bill we find that the Pathological Institute has escaped the destroyers's hand, but it has escaped as if by fire. For we read: "For the Pathological Institute, twenty thousand dollars, or so much thereof as may be necessary, no part of which shall be paid for rent." As the Institute has no home, save such as it acquires by "rent," the question arises: what is it going to do with itself? The State Commissioners in Lunacy have prepared this bill. Is it their intent to kick the Institute into the street? Or do they think that pathological institutes can live on a name regardless of a habitation? We await some word from that silent but mysterious body.

ECHOES AND NEWS.

NEW YORK.

Governor Roosevelt's Nominations.—The Senate confirmed on April 5th the following nominations made by the Governor: Dr. George Elmer Gorham of Albany, Hulbert E. Brown of Mt. Morris, Anson P. Thompson of Ellisburg and Mary E. Joy of Syracuse as managers of the

Craig Colony for Epileptics; Amory B. Houghton of Corning as manager of the Willard State Hospital; Charles F. Howard, M. D., of Buffalo as a member of the State Reformatory at Elmira.

Appointments at Roosevelt Hospital.—The trustees of Roosevelt Hospital at their recent meeting divided the surgical service of that institution and appointed Dr. R. F. Weir and Dr. W. T. Bull Visiting Surgeons. Both of these men are at the present time Visiting Surgeons to the New York Hospital and Professors of Surgery at Columbia University. The appointments will take effect April 16th.

Association of Military Surgeons.—The Association of Military Surgeons of the United States will meet at the New York Academy of Medicine May 31st, June 1st and 2d, 1900. The members of this organization are drawn from the national services of the Army, Navy, and Marine Hospital, and from the National Guard and militia of the several States.

Leper at Large.—Charles Serrattero, a Sicilian, feeling unwell, called at Bellevue Hospital for treatment on April 7th. After a careful examination the diagnosis of leprosy was made. He could not be received in Bellevue, so he returned to his home at 123 Elizabeth Street.

The Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons, Columbia University, for 1900, will be delivered at the New York Academy of Medicine on April 18th, 24th, and 26th, at 8.30 P. M., by Professor John G. Curtis, M.D., of Columbia University. Subject: "The Discovery of the Nerves and of Their Function."

Contagious Diseases.—For the week ending April 7, 1900: Measles, 715 cases and 31 deaths; diphtheria, 240 cases and 32 deaths; laryngeal diphtheria (croup), 22 cases and 15 deaths; scarlet fever, 164 cases and 14 deaths; chicken-pox, 23 cases; tuberculosis, 327 cases and 207 deaths; typhoid fever, 11 cases and 7 deaths; cerebro-spinal meningitis, 14 deaths; total, 1502 cases and 320 deaths.

Medical Legislation.—The bill providing for the establishment of a hospital in the Adirondacks for incipient tuberculosis has passed both houses of the Legislature, but the amount of the appropriation was reduced from $200,000 to $50,000. The New York State Medical Association was granted a charter. The bill appropriating $70,000 for the construction of a building at the quarantine station in New York Harbor for the detention of passengers was concurred in by both houses.

A Case of Burial Alive.—A report comes from Rochester, N. Y., that a well-known resident of Sandy Creek, a neighboring village, died January 4th after several weeks' illness from scarlet fever and was buried in the local cemetery. On March 31st the father of this young man died, and in order to make room in the family plot, it became necessary to move the body of the son. Upon disinterring the casket, the glass front of the coffin was front to be shattered in pieces, the bottom was kicked out, and the sides were sprung. Upon removing the lid, it was found that the body was resting on its face, the arms were bent at the sides, and in the tightly clinched fists were handfuls of hair, showing that a terrible struggle had taken place.

Tenement-House Bill Signed. — Governor Roosevelt signed on April 4th the bill authorizing him to appoint a commission to investigate the tenement-house problem of New York and Buffalo, and providing that the commission shall report to the next Legislature a new code of tenement-house laws. An appropriation of $10,000 is made for the expenses of the commission.

Old New York Doctors.—Dr. Sidney H. Carney, Jr., the new Recording Secretary of the New York Historical Society, has entertained its members with an interesting paper on physicians in New York one hundred years ago. The city contained several prominent physicians at that time, but judged by modern standards, medicine was in a very crude state. In 1800 there were only five medical schools in the United States. The first was at Kings (now Columbia) College, established in 1767; the second at Philadelphia, in 1768; the third at Cambridge, Mass., 1781; the fourth at Dartmouth College, N. H., in 1798, while a fifth was instituted the following year in Lexington, Ky. The first students to receive medical degrees in America were Samuel Kissam and Robert Tucker. They were conferred by Kings College. Among the professors in 1800 were Drs. Richard Bailey, John R. B. Rodgers, Wright Post, William Hammersley, Samuel L. Mitchell, and David Hossack. There were thirty-four students that year, an increase of thirteen from 1799. Dr. Bailey died in 1801 from yellow fever, contracted while discharging his official duties as Health Officer of the Port. Dr. Wright Post was considered the most noted surgeon in the city in 1800, with the possible exception of Dr. Richard Kissam. Dr. Hossack was graduated from Princeton, received his medical degree in Philadelphia in 1791, and then studied abroad. Upon his return to New York he brought with him the first cabinet of minerals ever seen in America, as well as a collection of plants. He held several professorships in Columbia, and established and maintained for several years the well-known Elgin Botanic Garden, situated between what are now Forty-seventh and Fifty-first Streets, and running from Fifth Avenue to within one hundred feet of Sixth Avenue. Some twenty acres were under cultivation, and it is related that he always closed his spring course of lectures with a strawberry festival in order that the students might see "that we are practical as well as theoretical." He was one of the founders of the New York Historical Society in 1804, and his house was the resort of the learned of all parts of the world.

Errata.—In Dr. Abbe's article which appeared in our last week's issue the percentage of cases of pure carcinoma of the breast that had reached the three-year limit without recurrence, after operation, was stated at 25 per cent. This should have read 50 per cent.

PHILADELPHIA.

Reception to Dr. Martin.—Dr. John C. Da Costa, President of the Obstetrical Society, tendered a reception to Dr. F. H. Martin of Chicago, April 5th. The reception followed the meeting of the Society at which Dr. Martin gave his address and was attended by the prominent obstetricians of the city.

Health Report.—The deaths in the city for the week ending April 7th were 732, an increase of 53 over the previous week and of 143 over the corresponding week of last year. Contagious diseases: Diphtheria, 86 cases, 22 deaths; scarlet fever, 73 cases, 6 deaths; typhoid fever, 89 cases, 11 deaths. Influenza was reported as being the cause of 42 deaths.

Smallpox Report.—The March report of the State Board of Health gives the statistics of smallpox for the month as 33 cases and 3 deaths. These cases were in eleven districts and widely scattered throughout the State. Philadelphia had three cases.

University Surgical Teaching.—The University of Pennsylvania is to have a professor of surgery and two professors of clinical surgery, which practically creates a new chair in the Faculty. It is rumored that Dr. J. William White, Clinical Professor, is to be made professor of surgery in the place of Dr. John Ashhurst, Jr., who lately resigned.

Jefferson Faculty Changes.—Two additions have been made to the major Faculty of the college. Dr. F. X. Dercum, formerly Clinical Professor of Diseases of the Nervous System has been elected Professor of Neurology, and Dr. J. Chalmers Da Costa, Clinical Professor of Surgery, was elected Professor of the Principles of Surgery and of Clinical Surgery.

Nurses' Home.—The Pennsylvania Hospital has secured ground on which will be erected an elaborate home for the nurses of the institution, fifty of whom are now occupying temporary quarters. The hospital is constantly expanding, 28,000 patients being cared for during the past year.

Obstetrical Society.—At the meeting of April 5th the Society was addressed by Dr. F. H. Martin, of Chicago, his topic being "Removal of the Bladder with or without Hysterectomy in Order to Extend the Possibilities of Surgery for Malignant Disease of the Pelvis." The operation is a formidable one but is justifiable when the condition in the pelvis is more formidable. The points considered by the speaker were, first, would the removal of the bladder make a more extensive operation possible; second, the immediate difficulties to be overcome in such removal and its remote effects; third, the operative technic. In cancer of the uterus involving the bladder the removal of the uterus is only a makeshift. By the operation suggested the bladder, the urethra, and an inch of the ureters, can be removed in addition to the uterus. The immediate difficulty is the disposal of the ureters. The rectum or sigmoid flexure is considered the best place to divert them, as it offers reservoir room, emptying power, and voluntary control of the reservoir. The objection to this has been the danger of ascending urethritis. Experimental work upon more than 60 dogs has demonstrated that the requirements of the occasion will bring about an increased resistance on the part of the ureters such as is seen in cases of exstrophy of the bladder. Experimental work on animals is unsatisfactory, however, owing to the changed conditions of gravity, inability to keep the rectum clean, and to retain catheters in the ureters for several days after the operation. In the transplantation of the ureters into the bowel the ends of the ureters are approximated for a distance of from 2 to 3 cm. and buried for an inch or more in the muscular coats of the bowel. The fecal mass as it passes this place squeezes out the contents of the ureters in the direction of the fecal current, and after it passes the urine spurts forth and thus upward infection is rendered less liable. The fear of absorption of the urine from the bowel is not well founded and it is believed that the sphincter will retain the urine. The extirpation of the bladder and uterus is advised in cases where cancer has involved either organ and extended to the other. All diseased tissue that can be removed should be taken away even if this does not include it all. Preparation should be made for a desperate operation, transfusion used, and the best assistants secured. The conclusions are: (1) The operation is justifiable under certain desperate circumstances. (2) The ureters should be transplanted into the rectum. (3) The amount of pelvic tissue removed is materially increased. (4) The operation should not be undertaken by one who does not thoroughly understand the technic and who has not done considerable experimental work upon animals. In the discussion of this paper Dr. E. E. Montgomery considered the method of ureteral transplantation as a great advance in surgery, but thought the mortality too great to justify extirpation of the bladder. Where malignant disease of the uterus has spread to the bladder the parametral tissues are so involved that even this operation would probably not be successful. If the patient's life should be prolonged for only a short time with the probability of recurrence of the disease, an operation of such gravity would not be indicated. Dr. John Clark stated that the paramount point is the removal of the local involvement. If the disease has spread to the lymph glands it is incurable. When it has gone so far that removal of the bladder is indicated, the anemia and ca-

chexia of the patient would contraindicate such an extensive operation.

CHICAGO.

Rush Faculty Changes.—The office of vice-president is established, and Dr. Henry M. Lyman, Dean of the Faculty, in view of his long connection with the college and the valuable services rendered is appointed to this office. Dr. Frank Billings, Dean of the Senior class is promoted to the deanship of the Faculty. Dr. John M. Dodson and Dr. Frederic S. Collidge are reappointed Deans in charge of the Freshman class. The resignation of Dr. Norman Bridge as Professor of Medicine is accepted and he is appointed Emeritus Professor of Medicine. Dr. John M. Dodson has been appointed to the Professorship of Pediatrics; Dr. D. R. Brower to the Professorship of Mental and Nervous Diseases.

Chicago Medical Society.—At a meeting, held April 4th, Dr. Geo. E. Shambaugh presented a case of unilateral chronic suppuration of the frontal, maxillary and sphenoid sinuses with no complications. The patient, twenty-two years of age, dated her trouble back ten years, when, after an attack of typhoid fever, she began to have a purulent discharge from the right side of the nose which has continued ever since. During this time she has suffered a great deal from headache and from dry pharyngitis and has been unusually subject to attacks of acute rhinitis. When first examined a mass of polyps completely filled the right side of the nose. These polyps and a degenerated middle turbinated body were removed, when creamy pus was seen oozing from the middle meatus of the nose, showing that some of the accessory sinuses were affected. Two weeks later the patient was again examined, when, after thoroughly cleaning the right side of the nose, pus was seen to appear at three separate points. These points proved to be the normal openings into the sphenoid, the frontal and maxillary sinuses. A soft silver cannula, curved at the proper angle, was introduced into the maxillary and frontal sinuses through their normal openings and pus was washed out from each. The case was one of simple chronic suppuration in these three accessory sinuses, with no complications and no involvement of the overlying structures which would point to disease of the sinus, and the diagnosis was made by direct intranasal methods. A skiagraph of the case was exhibited, showing the position of a probe passed through the frontonasal duct into the frontal sinus.

Double Cryptorchism Complicated by Scarlet Fever.—Dr. Edward H. Ochsner reported a case and exhibited a patient who was operated upon for double cryptorchism and who, twenty-four hours later, developed scarlet fever. The patient, a boy, thirteen years of age, whose family history and previous history were good, was operated upon for double cryptorchism on January 26, 1900. On the day before the operation the patient was perfectly well except for a very slight cough, which was attributed to a slight cold. The heart and lungs were normal.

The ordinary operation was performed. Patient vomited only once or twice from the anesthetic, but coughed a great deal during the following night and did not sleep well. Apart from this he did well until eighteen hours after the operation, when his temperature quite suddenly rose to 101° F. and the pulse to 102. Thirty hours after the operation the temperature was 104 and the pulse 120. Patient had a peculiar strawberry-tongue and a very congested throat. The following morning, forty-eight hours after the operation, patient was covered with a scarlet rash. Thirty-six hours after the operation Dr. W. J. Class made a culture from the patient's blood and obtained an uncontaminated growth of the Class diplococcus scarlatinæ. Nine days after the operation the patient's temperature and pulse were practically normal, but typical scales began to develop and continued to exfoliate for several weeks. From these also the diplococci were cultivated. The patient made an uneventful recovery. The case is reported in order to emphasize the importance of a bacteriologic examination in all cases of so-called septic rashes, many of which are undoubtedly exanthemata.

The Bone-Coupler in Intestinal Resection.—Dr. Jacob Frank reported a case of double pyosalpinx with tubo-ovarian abscess complicated with such firm peritoneal and intestinal adhesions that resection of the bowel was necessary. The intestines were found to be very friable and infiltrated, so that it was decided to do an intestinal resection. The anastomosis was effected by means of the Frank decalcified bone-coupler, 1⅛ inches in size, was used, having determined the measurement by means of the Frank enterometer. The operation was completed by draining with a Mikulicz and a glass drain. The piece of rubber tubing was passed on the fifth day following the anastomosis. The patient left the hospital five weeks after the operation.

GENERAL.

Canadian Medical Association.—The next meeting of this society will be held at Ottawa on September 12, 13, and 14, 1900. This will be the centennial meeting of the Association and an effort is being made to properly celebrate the occasion. It is expected that Dr. Edmund Owen, of London, England, will deliver the address in surgery.

The Plague at Honolulu.—It is estimated that the cost of suppressing the plague at Honolulu will amount to $2,000,000. Heavy expense has been incurred in building detention camps and supplying provisions for the people detained. It was necessary also to provide accommodations for those who lost their homes by the fires. March 31st was the sixth day since the appearance of the last case of plague and the Board of Health expressed confidence that they had reached

the end of their contest. Since December 12th there had been seventy cases of plague, of which sixty died.

The Army Hospital Ships.—It appears that neither of the two army hospital ships is available for bringing home sick soldiers from the Philippines, and the War Department is arranging to have such service temporarily performed by the transports plying regularly between Manila and San Francisco. The "Missouri" has been practically condemned and it is possible that she may not be retained in the military service. The "Relief" is now in the Philippines. Owing to her limited coal capacity, it is not deemed expedient to send her across the Pacific with a load of invalids.

Hydrogen Solidified.—Professor Demar solidified hydrogen before the Royal Institution in London on April 7th. He surrounded a tube containing liquid hydrogen with liquid air, to prevent the ingress of heat, and then by means of a powerful air pump transformed the liquid hydrogen into a white, opaque solid.

Trained Nurses Wanted in Cuba.—Application for trained nurses of both sexes to go to Cuba has been made by St. J. Greble, Assistant Adjutant-General and Superintendent of Hospitals and Charities at Havana. The applicant desires to place in each of the hospitals and orphan asylums in Cuba which contains more than one hundred inmates, a trained nurse "who will be able to straighten out the present deplorable condition of most of these institutions."

Dissection in New Jersey.—Dr. C. F. Adams, of Trenton, N. J., writes that the statement made in the issue of the Medical News, March 24th, that dissection is prohibited in New Jersey is not strictly correct. Dr. Adams was instrumental in having a law passed by the Legislature five years ago regulating the dissection of dead bodies. By its provision the bodies of persons dying in public institutions may be utilized as dissection material by certain societies definitely organized for such purposes. Upon the passage of the law a society was immediately organized and incorporated, rooms were secured, and considerable work accomplished. The society is still in existence and is able to secure an abundance of material without difficulty.

Insanity in the Army.—Secretary Root has had prepared a statement which fully disproves the many charges that have been made as to a large percentage of insane and suicide cases in the army. It shows a smaller rate of insanity among the troops in the Philippines than in the regular army for ten years. From July, 1898, to March 20, 1900, thirty-five cases of insanity have been reported in the Philippines. During this period the mean strength of the force under General Otis was 32,000 men. Based on this strength the rate of insanity for twelve months was 31.3 cases. The mean strength of the regular army for the ten years ending July, 1898, was 29,000 men with a rate of insanity of 33.1. Seven officers and 22 enlisted men committed suicide in the Philippines between April 11, 1899, and March 27, 1900.

Water Filtration.—The *Scientific American* in commenting upon the results of the recent instalment of the filtration beds in connection with the water supply of Albany, N. Y., says: "The disease directly traceable to the sewer polluted water of the Hudson was typhoid fever, the death-rate from which the city of Albany for nine years ending 1898 had averaged 85 per annum. During the first four months in which the filters have been in operation, 7 deaths from this cause have been reported. During the corresponding interval of the nine years ending 1898, the average number of deaths was 24; so that the filtration of the water has reduced the deaths from this cause in the ratio of 24 to 7. The filtration plant at Lawrence has reduced the typhoid fever death-rate in that city from 11.31 to 2.54. The filtration plant in the city of Hamburg, Germany, was put in operation in 1895; during the five years previous to that date the average typhoid death-rate was 4.72, since that date it has fallen to .72. Since the opening of the filtration plant of the city of Mount Vernon, N. Y., in 1894, the number of deaths from typhoid has decreased over 76 per cent. The average cost of operating the filters at Mount Vernon, including the laboratory work, is $1.67 per 1,000,000 gallons."

The American Gastro-Enterological Association.—The third annual meeting will be held in the banquet hall at The Shoreham, Washington, D. C., Tuesday, May 1, 1900. The following is the provisional program:

1. The Occurrence of Mould in the Stomach and Its Probable Significance. Max Einhorn.
2. Sugar, as Such, in the Dietary of Dyspeptics. Wm. Gerry Morgan.
3. Concerning the Nature of the Biologic Cell Processes in Malignant Neoplasms, and Their Significance for the Early Diagnosis of Cancer of the Stomach. J. C. Hemmeter.
4. The Appendix and Cecum from the Standpoint of the Gastro-Enterologist. A. L. Benedict.
5. Feeding the Sick. A. P. Buchman.
6. Starvation versus Feeding in Diseases of the Stomach—Illustrated. Frank H. Murdoch.
7. A Case of Cancer of the Esophagus; perforation into the left Pleura; death from Pyopneumothorax. Exhibition of Specimen. Julius Friedenwald.
8. Some Clinical Observations on the Position and Topography of the Stomach. G. W. McCaskey.
9. Remarks on Stenosis of the Pylorus. Henry W. Bettman.
10. Report of an Interesting Case. E. G. Cutler.
11. Mechanics of Digestion. F. B. Turck.
12. Epigæa. Charles D. Aaron.

Medical War News.—What appears to be the first serious reflection upon the sanitary man-

agement in the South African war is the recent outbreak of typhoid fever among the Boer prisoners on shipboard off Simonstown. Over one hundred prisoners are prostrated with the disease, many deaths have already occurred, and fresh cases are developing daily. Nowhere is the water supply so absolutely under control and easy of inspection as upon shipboard, and in view of the well-known fact that some of the South African towns are not above suspicion in regard to typhoid and a polluted water supply, every precaution should certainly have been taken to guarantee the purity of drinking-water taken on board the prison ships. On the other hand, it may be quite possible that the prisoners were already infected before being brought to Simonstown. Enteric fever has certainly been rife in most of the Boer laagers, due to the carelessness in infecting their sources of water supply. The matter should be strictly investigated, for an outbreak of a preventable disease like typhoid among the prisoners of war of a great and enlightened nation is, to say the least, unfortunate, especially when contrasted with the absence of any serious disease among the prisoners at Pretoria.

The hospital ship "Maine" has been ordered home to England, with a consignment of invalids on board. This is occasioning some surprise, and it seems a pity in view of the rapid progress made by the wounded and fever cases in the sea breezes at Durban that she should not be allowed to remain as a floating hospital. Transports are returning almost empty each week and could comfortably carry back cases of delayed convalescence and hopelessly chronic affections. The immediate reception and care of cases in the acute stage seems to be a more appropriate service for hospital ships, instead of being employed as "mere beasts of burden" for the long voyage home. It is quite possible, however, that the "Maine" has on board a sufficient number of patients who could not safely be transferred to the transports, or trusted to their crude hospital accommodations to bring them home in comfort.

Dr. Jameson, the leader of the famous raid into the Transvaal territory, has recently arrived at Cape Town seriously ill. The presence of pneumonia in increasing severity and prevalence among the rank and file of the British army is becoming serious. The approaching winter season and great elevation of the country are productive of cold nights, against which proper provision has not been made.

American Climatological Association.—The seventeenth annual meeting of the Association will be held in the banquet room of the Arlington Hotel, Washington, D. C., May 1, 2, and 3, 1900. The program is as follows: President's Address, Abraham Jacobi, New York.

The Modern Physician's Duty to His Tuberculous Patients. Frederick I. Knight, Boston.

The Construction and Management of Small Cottage Sanatoria for Consumptives. Arnold C. Klebs, Chicago.

A Report of Certain Cases of Tuberculosis Which were apparently due to the Nature of the Soil. Richard Cole Newton, Montclair, N. J.

The Educational and Legislative Control of Tuberculosis. Charles Denison, Denver.

Some Phases of the Tuberculosis Problem in Colorado. Sherman G. Bonney, Denver.

Some Personal Observations on the Effect of Intrapleural Injection of Nitrogen Gas in Tuberculosis. H. P. Loomis, New York.

Bacterio-Therapeutics, with Especial Reference to Tuberculosis. E. R. Baldwin, Saranac, N. Y.

(To be read at the general meeting of the Congress, on Tuesday afternoon, May 1st.)

Subsequent History of Patient Apparently Cured by Antitubercle Serum. J. Edward Stubbert, Liberty, N. Y.

Stomach Conditions in Early Tuberculosis. Boardman Reed, Philadelphia.

The Phlebitis of Advance Phthisis, with Report of Cases of Phthisis following Abscesses of the Hand. R. G. Curtin, Philadelphia.

Report of a Case of Spleno-myelogenic Leucemia with Tuberculosis, with Remarks on Blood Examination in Tuberculosis. H. L. Elsner, Syracuse.

The Hydriatic Treatment of Tuberculosis. J. H. Kellogg, Battle Creek, Mich.

Petroleum Oil in the Treatment of Phthisis. W. D. Robinson, Philadelphia.

The Inadequacy of the Physical Signs as Indicating the Gravity of Pneumonia. Andrew H. Smith, New York.

The Blood Changes in High Altitudes. S. E. Solly, Colorado Springs.

The Bath in Gout. Charles C. Ransom, New York.

A Case of Mural Endocarditis. Harold Williams, Boston.

Exercises Suitable for Children Suffering from Heart Disease. J. Madison Taylor, Philadelphia.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, March 31, 1900.

FIRST ANNUAL MEETING OF THE POLYCLINIC—DEFEAT OF COUNTY COUNCIL WATER BILLS—A "JUBILEE" MEDICAL DIPLOMATIST—FAREWELL ADDRESS OF SIR WILLIAM GAIRDNER—CANDIDACY OF PROFESSOR OSLER—AWARD OF ARBITRATOR IN THE "PHOSSY JAW" HEARING.

The first annual meeting of the London Medical Graduates' College and Polyclinic has just been held and a most encouraging report of progress presented. Sir William Broadbent, the President, announced that 607 members had been enrolled, a commodious and centrally-situated building purchased and equipped, and five course of lectures, classes, and clinics, held dur-

ing 1899. The attendance at the public consultations had been excellent, reaching as high as nearly 400 per week, and an abundant supply of interesting and, in many instances, rare and unusual cases had been secured. Practitioners of medicine were coming to appreciate and avail themselves extensively of these opportunities for securing expert opinions in the cases of patients who were too poor to afford a consultant's fee.

As the sessions of the College were only opened in May last, the financial statement is naturally large one of expenditure, but a gratifying number of donations have already been received, both from the profession and the public, a small but increasing income already secured, and the future prospects of the infant institution are most favorable, considering the extreme youth and slowness with which the conservative British mind "catches on" to a new departure. It has had to run the gauntlet of strenuous opposition from all the great teaching hospitals and their schools, and from the great body of consultants in London, but this is now dying down as the aims of and necessity for the College are becoming better understood, and the fact that it has not only survived, but steadily prospered in the face of it, is a proof of its vigor and vitality which renders its future practically assured.

After a prolonged debate Parliament has again refused to do anything for the relief of London in the matter of its water supply. Both the bills put forward by the London County Council, the first for purchase by the Council of the existing plant, and the second for securing a supply from Wales, were defeated. This leaves the metropolis at the mercy of the present companies and the vagaries of the tiny Thames and rivulet-like Lea, with the vague recommendation by the late Royal Commission of purchase upon exorbitant terms, by some nebulous body which is yet to be created but which is *not* to be the County Council, as the only prospect for future relief. This is the third time a similar bill has been presented by the Council and defeated, but, as the majority against it this time was much smaller than was expected, three or four more years may possibly see it passed by Parliament. The control of the two great English-speaking world-capitals, New York and London, by outside legislative bodies, although it has its advantages, is a terrible drawback in the main.

The phenomenal security and length of tenure of all positions connected with the English diplomatic service was illustrated in a member of our own profession this week by the death of Dr. Edward D. Dickson who for *forty-four years* had held the post of Physician to the British Embassy at Constantinople; and he had been physician to other Consulates for *nineteen years* before that. Dr. Dickson was an energetic and trusted servant of the Government, which had availed itself of his services as commissioner and delegate to a number of boards and conferences, political, as well as medical and sanitary, notably the Conference upon Asiatic Cholera, in 1866, and the Ottoman Quarantine Tariff Commission in 1867. But think of retaining official connections with the diplomatic service since the accession of Queen Victoria, sixty-three years, and in a foreign land at that!

By a strange coincidence, the same session in which the Chair of Medicine in Edinburgh became vacant by the death of Sir T. Grainger Stewart sees the same chair in the sister university of Glasgow vacated by the voluntary resignation of Sir William Gairdner. This was formally intimated to his class in an almost pathetic little farewell address in which he stated that, although his enjoyment of the stimulating work of teaching was as keen as ever, the difficulty of keeping in touch with the enormous output of literature representing the rapid advances in all departures of recent medicine, especially in that of bacteriology, was fast becoming an impossibility because of his failing eye-sight, and he therefore felt that he ought to resign in favor of "at least a younger pair of eyes and, perhaps, a younger brain."

Sir William Gairdner's intention to resign was privately intimated some weeks ago, but it will be surprising if the Court of the University accept his resignation. The very fact of his being capable of withdrawing upon such noble and self-sacrificing grounds stamps him as simply invaluable to any teaching body. A veteran teacher of his long-proved ability and immense experience who, with the modesty of true greatness, is conscious of the limitations of age, is worth a dozen laboratory-made, up-to-date young prodigies, full of the boundless confidence of youth.

The telegram of Professor Osler to the *British Medical Journal*, stating that he is not a candidate for the Chair of Medicine at Edinburgh, will be received with general regret by the profession here. His work is as widely known and as highly admired here as at home, and he would have been most cordially welcomed as a permanent addition to the ranks of British medicine.

The award of the arbitrator, appointed by the Home Office to hear the objections of the manufacturers to the rules passed by the last Parliament for the prevention of phosphorus-poisoning in the match industry, has resulted in a substantial sustaining of the regulations as they stand. These provide for the regular and frequent inspection of the jaws and teeth of the workers by both a dentist and surgeon, as the evidence of all witnesses was overwhelming that practically the sole risk of "phossy jaw" lay in decaying teeth and ulcerated gums. Careful provision is to be made for fan-ventilation of the rooms used for the dangerous processes, mixing the paste, dipping and drying, and these are to be separate from the rest of the factory and, so far as possible, open to the sky. Employers are to provide overalls for all workers in the dangerous branches and these are to be washed every week and removed before eating, while a fixed minimum of lavatory, dining-room, and cloak-room accommodation is to be provided. That preven-

tion is practicable and possible was abundantly proved by the experience of one factory, that of Bell & Company, where, by taking most of these precautions, only one case of "phossy jaw" had occurred in thirty-three years, and we may look forward with hopefulness to seeing this blot upon our industrial system effaced in the near future.

TRANSACTIONS OF FOREIGN SOCIETIES.

German.

A CASE OF DIVIDED STERNUM—HEMORRHAGIC EROSIONS OF THE STOMACH—SIX SUPERNUMERARY BREASTS—NEW METHOD OF DEMONSTRATING THE ACCESSORY NASAL CAVITIES—EFFECT OF GELATIN INJECTIONS ON AN ANEURISM OF THE AORTA.

At the British Medical Society, February 21st, R. Virchow presented a man aged forty years whose sternum was completely divided through the long axis by a fissure. The pulsations of the heart transmitted through the overlying skin were plainly visible. This severe congenital anomaly gave the patient no disturbing symptoms.

C. Pariser spoke of hemorrhagic erosions of the stomach, which usually occur in large numbers and are not confined to any one part of the stomach. They may lead to death by hemorrhage. Thus far the diagnosis has been made only at autopsy. The symptoms are these: The patients complain of very severe pain about half an hour after taking any food. The pain is described as a burning-hot one, but not confined to any part of the stomach; nor is it cramp-like. It lasts about two hours. It ceases at once if the stomach is irrigated. Irrigation, when the stomach is empty, will bring out a water faintly tinged with blood, and containing a few shreds of mucous membrane. Sometimes the amount of hydrochloric acid is reduced; sometimes it is above normal. The pain is caused by the contact of gastric acids and those in the food with the ulcerated areas in the stomach. Through fear of pain patients get into the habit of eating very little and so grow thin. The affection is not an independent one but is a complication of chronic gastric catarrh. The erosions heal without leaving a scar. They rarely deepen into a chronic ulcer. The best treatment is irrigation of the stomach with a solution of silver nitrate, 1-2000, 1-1500, or 1-1000. Two pints should be introduced, one after the other, and when the second has been drawn off the stomach should be washed with salt solution. Dietetic treatment is invaluable. The food should be absolutely bland. If these measures do not suffice the patient should be put upon the same treatment as is followed in gastric ulcer.

Benas showed a patient February 28th who had three pairs of supernumerary breasts, situated above and externally to the normal breasts and in three stages of development. The lowest two were simply pigmented areas, the next possessed rudimentary nipples, and the third and largest pair presented breast glands and nipples from which milk flowed in abundance. The glandular tissue was situated well up in the axilla. When lactation ceased the extra breasts grew smaller and stopped secreting milk. This is an example of atavism. Similar epithelial inclosures have been found in the embryo. Sometimes heredity seems to play a part.

March 7th, G. Bruhl exhibited a number of skulls which he had prepared by a new method in order to show the size and position of the cavities which communicate with the nose. The bones were made transparent by decalcification and soaking in xylol, and the para-nasal cavities were filled with "Wood's metal." The mean capacity of the frontal sinus was found to be 2.8 ccm., that of the antrum in the superior maxilla, 10.5 ccm., and that of the sphenoidal sinus, 1.9 ccm. The total volume of all the accessory cavities is about 45 ccm., which is a sufficient explanation of their importance in diseases of the nasal apparatus. This method of demonstration of these cavities is far superior to any at present in use.

At the Union for Internal Medicine at Berlin, February 26th, A. Fraenkel showed a specimen from a patient who had received during a long time gelatin injections in order to cure an aneurism of the arch of the aorta. The patient was a man aged fifty-three years, who became infected with syphilis at about his twentieth year and thereafter suffered from many secondary and tertiary lesions, in spite of a great deal of antisyphilitic treatment. In July, 1899, he suffered so from an aneurism of the aortic arch that he entered a hospital. He was put to bed and was given an injection of 50 ccm. (oz. 1-jss) of a one-per-cent. solution of gelatin twice a week. In six weeks he had improved so much that he refused to remain longer. After two weeks of running about his symptoms came on in full measure and he returned to the hospital. He was again put to bed, and was given injections twice weekly of a two-per-cent. solution of gelatin. Again dyspnea disappeared, the size of the tumor seemed to grow less, and after twenty-six injections the patient was allowed to get up and go about. The improvement was short-lived and the patient soon began to have attacks of suffocation, in one of which he died. The aneurism was found to occupy the whole arch of the aorta. Over the whole of its inner surface there was a deposit of fibrin 1.5 cm. (0.6 in.) thick. Fraenkel hesitated to affirm that the gelatin injections had caused the desposit of fibrin.

Litten said that the only therapeutic resource which seemed to him to benefit a patient with aortic aneurism is rest in bed. All the methods which have been brought forward to facilitate coagulation in the sac, injection of chemicals into the sac, or of fibrin ferments or ergotin, electrolysis or electropuncture, and, finally, the introduction of foreign bodies into the sac, have failed in his hand to make good the statements of their

advocates. He had tried gelatin in four cases. None of the patients had died, but none was improved by the treatment. He did not believe that the layer of fibrin in Fraenkel's case was due to gelatin injections, as it is often found in aneurismal sacs of patients who have not received injections of gelatin.

SOCIETY PROCEEDINGS.

THE NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held Monday, March 19, 1900.

(Continued from p. 560.)

Diphtheria Antitoxin.—Dr. W. H. Park of the New York City Department of Health said that the final test of the value of diphtheria antitoxin must be the chemical results of its use. There are many factors that must be taken into account before a definite conclusion can be reached in the matter. In laboratory experiments diphtheria antitoxin undoubtedly does good. To many minds there remains a doubt as to whether the diphtheria bacillus is really the cause of diphtheria or not. In two involuntary laboratory experiments made on human beings in the Health Department of the City of New York severe diphtheria was contracted by the inadvertant sucking up of virulent bouillon cultures of diphtheria bacilli into the mouth. Hence, it would seem, despite the fact that in a third such instance no diphtheria resulted, that the diphtheria bacillus is the cause of the disease. There are undoubtedly diseases that strongly simulate diphtheria, but they do not possess all the characters of diphtheria and can be differentiated even clinically from that disease. Just as cases of pneumonia may be due to the pneumococcus or to the influenza bacillus, so membranous formations in the throat may be produced by various microbes. Diphtheria antitoxin neutralizes diphtheria toxin even outside the body. A mixture of the two may be injected into animals without danger, hence, the lesson to inject diphtheria antitoxin as soon as possible so as to prevent the diphtheria toxins from producing serious deleterious effects before they are neutralized. Besides, secondary infections are not affected by the diphtheria antitoxin. Hence, this remedy should be used early and before the occurrence of secondary infection for which the diphtheria is a predisposing cause. That the belief in diphtheria antitoxin is not a mere fad may be gathered from the fact that while its advocates have so much confidence in diphtheria antitoxin, they do not consider the other antitoxic sera to be of any very great value in human therapeutics.

Statistics of Diphtheria Antitoxin.—In New York for twenty years before 1895, the actual number of deaths from diphtheria each year remained about the same, that is, despite the increase of population there was no actual increase in the mortality from diphtheria. There was a certain periodicity in its fatality. About every sixth year the number of deaths reached three thousand. The mortality ran down to about two thousand in certain years, and averaged about 2400. The lowest mortality in any one year was 1600. In 1894 before the introduction of antitoxin the number of deaths was 2870. During these last four years the average number of deaths has been 1300, that is, more than 1000 less than the average of preantitoxic days. In Boston a similar decrease in the number of deaths has taken place, and the percentage mortality from diphtheria is now less than 4 per cent. Not all the decrease in the number of deaths is due to antitoxin. No one claims this. A certain amount of the decrease in the mortality is due to better hygienic surroundings in the large cities. It is a very striking fact, however, that such a notable decrease in the death-rate from diphtheria should have occurred immediately after the introduction of antitoxin and that this decreased mortality should have continued ever since. Last year in New York 2500 children were injected with antitoxin. Of these 300 died. Without antitoxin the mortality would have been at least double what it was. The death-rate even in laryngeal diphtheria was only 22 per cent., while formerly this type of the disease was fatal in over 60 per cent. of the cases here in New York. Six thousand five hundred children were immunized by injections of diphtheria antitoxin. Of these 28 cases developed the disease within twenty-four hours and all of them recovered; 27 children developed the disease after the lapse of twenty-four hours and all of these recovered with one exception in which scarlet fever complicated the diphtheria. All of these children were directly exposed to contagion, yet over 6400 failed to take the disease. As the result of the immunization some rashes developed and in a few cases some febrile reaction was noted, but nothing lasting supervened.

A good deal of dispute has arisen with regard to the effect of diphtheria antitoxin at the Willard Parker Hospital. Before the introduction of antitoxin the mortality from diphtheria was 30 per cent.; since then it has been 22 per cent. The mortality of cases of intubation for the six months before the introduction of antitoxin was 85 per cent. During these last two years the mortality among these cases has been 52 per cent. Last summer the crucial test was made of taking each alternate diphtheria patient that came to the hospital and treating one series with and the second series without antitoxin. It was very clear to the whole staff that the children that received antitoxin did better than those that were treated without antitoxin. In Boston the hospital mortality from diphtheria is 12 per cent.

Innoxious Serum.—The desideratum now is a serum that will do no harm while accomplishing the good it can do. The only safeguard is to have clean and sterile serum not over six months old. Not that serum deteriorates with age, but

that there is less of it after standing and one can not be sure of the number of units employed. The Health Department uses no antiseptic in its serum, so that the old contention that whatever effect is produced by the antitoxin is due to the carbolic acid used for preserving it now falls to the ground. Certain sera for reasons not well understood produce rashes. It is the present effort of the Health Department to get rid of the sera that produce these undesirable effects. The only way to eliminate them is by actual test of samples of serum.

Amount of Antitoxin.—In mild cases 1000 to 2000 antitoxin units are to be used. In severe cases 2000 to 3000 units. If necrosis is occurring 3000 to 4000. If twelve hours after the administration of the antitoxin there is no change in the symptoms noted, the dose should be repeated. Twelve hours later it may be repeated once more. As a rule, in children under one year not more than 3000 units should be given at a single dose. In children under six months not more than 2000 units should be given at one time. Advantage should be taken of the fact that a moderate dose of serum will give immunity for at least two weeks, to protect other children of a family who may be exposed to the contagion.

Yellow-Fever Antitoxin.—Dr. Fitzpatrick, as a substitute for Dr. Alvah H. Doty, Health Officer of the Port of New York, who was unavoidably absent, described some experiments made with the serum of the bacillus icteroides at Swinburne Island in New York Harbor and at Vera Cruz in Mexico. (The observations at Vera Cruz were published in the Medical News.) The results as a whole show that no influence is exerted on the disease by the serum. The serum is exactly the same as that used by Sanarelli who reported very satisfactory results from its use in South America, treating 22 cases of yellow fever with six deaths. Archinard in New Orleans also observed no special benefit from the use of serum prepared by Sanarelli himself. Dr. Wasdin of the United States Marine Hospital service used Sanarelli serum in three cases of yellow fever, but without satisfactory results. The injection of the toxin of the bacillus icteroides into patients convalescent from yellow fever gives the falling temperature with rising pulse which is pathognomonic of yellow fever. This specific reaction would seem to substantiate the claim that Sanarelli's bacillus icteroides is pathogenic for yellow fever.

Haffkine's combination of a serum obtained by the use of the bacillus icteroides and the bacillus coli communis has not yet been used on human beings, although it has given some encouraging results according to its inventor, at least, in the laboratory. Agramonte reports four cases of yellow fever treated with human serum taken from patients convalescent from yellow fever. The cases are too few to draw any conclusions from them, and besides no decided benefit was noted after its use.

Typhoid Serum.—Dr. William H. Welch of Baltimore sent his regrets for not being able to attend the meeting, and a note stating that in his opinion there is no satisfactory evidence of the clinical or laboratory value of any typhoid serum so far prepared. A vaccine recently invented seems to be more promising, but, as is evident, a long series of observations will be needed before its definite value can be decided. There is enough known of the subject to encourage further observation, but that seems all that can be said.

Antirabic Serum.—Dr. R. J. Wilson, of the Health Department of the City of New York, said that animals had been inoculated with rabies and then the serum collected with the idea that it would prove curative of the disease. The results so far obtained are extremely doubtful. The subject is one of the greatest interest, because once the symptoms of rabies have developed the Pasteur preventive treatment fails of its purpose. It is to be hoped, then, that the antirabic serum used in combination with the preventive treatment may retard the invasion of the disease, and so give preventive inoculations time to effect their prophylactic purpose.

Antistreptococcus Serum.—Dr. Howard Lilienthal said that he has no reason to change the opinion which he expressed with regard to antistreptococcus serum three years ago. He then said that it rarely did harm and that patients should be given the chance that its administration sometimes seems to afford. When patients to whom it is administered have only a local streptococcus infection, they all recover. Dr. Lilienthal, however, has never seen a single case of recovery when streptococci could be demonstrated in the blood. Certain inconveniences attach to the use of a serum. The troublesome urticaria is frequently noticed. Once streptococci were found at the point of inoculation in an abscess although the serum was proved surely sterile by failure of cultures from it. Streptococci were found in the blood of this patient, the abscess became large and phlegmonous, and the patient died on the eighth day. A good practical rule in cases of septicemia seems to be to open up the wound thoroughly and then if streptococci can be found in the blood or in the urinary sediment, give the serum. If there are no streptococci in the urine, await the result of the blood-cultures, unless the symptoms become alarming. Successful blood-cultures may be delayed from three to seven days.

Dr. William B. Coley gave the recent results of the mixed toxins in sarcoma. They appeared in a recent issue of the Medical News.

Technic of Injections.—Dr. Gibb said that not more than 500 to 1000 antitoxin units need be given at a single dose. The best place to give the injection is in the outer part of the thigh, inserting the needle to the depth of an inch and a half. The injection should be given very slowly, five to fifteen minutes should be taken for the purpose. The injection should be repeated in twenty-four hours and again in forty-eight hours, unless the symptoms show marked improvement.

Dr. Knopf said that he had had some experience with antituberculous and antistreptococcus serum, but his success with these remedies had not been such as to make him wish to use them to the exclusion of dietetic and hygienic methods. He had especially tried Marmorek's streptococcic serum for secondary infection of tuberculous lungs; and, while it seemed to give some reduction of temperature in cases where streptococci were found in the sputum, the definite results had not been very satisfactory. Experimentation along these lines must be continued, since it promises so much.

NEW YORK ACADEMY OF MEDICINE—SECTION ON MEDICINE.

Regular Monthly Meeting, Held Tuesday, March 20, 1900.

John H. Huddleston, M.D., Chairman.

The subject for the evening was a discussion on rheumatism.

Treatment in the New York Hospital.—Dr. Hughes Dayton said that the first and most essential part of the treatment for acute rheumatism in the New York Hospital is considered to be rest in bed, on a low diet consisting entirely of liquids. The drug-treatment is begun with a thorough purgation by salines. The salicylates are then administered. The usual form is the salicylate of soda in fifteen-grain doses every three hours, until the symptoms of fever and pain abate. If mental symptoms develop as the result of the fever, sodium bromide, thirty grains, is given with each dose of the salicylate. The tolerance for the salicylates is much better when administered in conjunction with the bromides. When for some reason the sodium salicylate is not borne well, salol is substituted, although this drug is usually given only in mild cases. Twice within the year, symptoms of poisoning with the salicylates have occurred. In neither case had they been administered in any considerable doses. These cases serve to show that it is not so much the absolute dose of the salicylates that cause the symptoms as it is a special susceptibility of the patient to their effects. In one case in which sodium salicylate seemed to be the cause of active delirium, the symptoms were very much lessened by large doses of sodium bromide. When sodium salicylate cannot be given salophen sometimes gives good results. When sodium salicylate is not borne by the mouth, it will sometimes be absorbed by the rectum without giving symptoms of irritation. Of late this method of administration has been successfully employed several times in the New York Hospital. Locally the application of methyl salicylate affords great relief from the pains. When the other salicylates cannot be taken by the mouth, the external application will sometimes of itself serve the purpose of ameliorating the pain. After the application of the methyl salicylate on a thin compress of gauze, it is covered with rubber-tissue and bound on. Absorption takes place very rapidly. Salicylic products can be noted in the urine thirty minutes after its application to the unbroken skin. If fluid persists in the joints after the acute symptoms have subsided, a cantharides blister will help to disperse it. For hyperpyrexia large doses of sodium salicylate are given besides a cold bath at 65° F. For the stiffness that follows acute rheumatism hot-air applications are usually employed. For subacute rheumatism the salicylates are not pushed to the extent to which they are used in acute cases. The alkali treatment is found to be very useful in these cases. Locally applications of methyl salicylate and hot-air baths give the most satisfactory relief of symptoms. For chronic rheumatism local hot-air treatment is employed and nutritious diet is provided, the alkali waters are given plentifully and the iodides freely prescribed. For muscular rheumatism salol and phenacetine are found to be of advantage, methyl salicylate is used locally; also belladonna ointment with good effect. It is in these cases particularly that counterirritation does good.

Treatment at the Mt. Sinai Hospital.—Dr. L. A. S. Bodine said that for acute articular rheumatism, first, calomel and salines are used to clear out thoroughly the intestines. Then fifteen to twenty grains of salicylate of soda is administered every four hours until the acute symptoms abate. Bicarbonate of soda is given in sufficient doses to make the urine alkaline and keep it so. Baths, at a temperature of from 75 to 90° F., help to relieve the acute symptoms. If eruptions occur and severe tinnitus aurium, the salicylates internally are replaced by external applications of oil of wintergreen, or by full doses of iodide of potash internally. For hyperidrosis, belladonna or its alkaloid is used. When the pain is very severe and persistent, phenacetine or antipyrine is employed. If the sleep is much disturbed, trional and the bromides are indicated. The patient is kept on an absolutely liquid diet, but is not limited to milk. On the contrary, a large variety of liquids are allowed, so as to avoid as far as possible the tendency to malnutrition so marked in rheumatism. Coffee is allowed once or twice a day, but it is apt to cause sleeplessness. All nitrogeneous food is avoided. The drinking of plenty of water is encouraged. The salicylates are always given well diluted and never on an empty stomach. The oil of gaultheria is employed for its local effect on the symptoms of the disease. When the effusion into the joints is extensive, tincture of iodine, firm pressure, immobilization and, as far as possible, elevation of the limb, are employed with very satisfactory results. For chronic rheumatism hot-air baths are employed and potassium iodide prescribed in reasonably large doses. Passive motion and massage help to restore mobility to the joints.

During convalescence from an attack of acute rheumatism one of the most important indications is the anemia that so commonly develops. For this, quinine, iron and strychnia are given. After forty-eight hours' remission of symptoms, eggs and starchy foods may be allowed, but no meats

until convalescence is well established. Chicken or turkey should be the first meats permitted. Out of 38 cases of rheumatism treated during the past year in Mt. Sinai Hospital, 29 were discharged cured and the remaining 9 were benefited.

Dr. J. J. Walsh then read a paper on

The Differential Diagnosis of Chronic Rheumatism.—It will appear in a subsequent issue of the Medical News.

Hot Air for Chronic Rheumatism.—Dr. Thos. L. Satterthwaite said the original use of hot air in medicine was suggested by Turkish baths and the first experiments were made with the simple warm chamber in which the patient was enclosed. As under these circumstances he would rebreathe the products of his own respiration, a box in which only the body or parts of the body were enclosed seemed more advisable. In a Turkish bath the temperature cannot be raised as a rule above 170° F. In the hot-air box parts of the body can be subjected to a temperature of 400° F. The main idea of all the mechanisms which have been invented for the purpose of giving hot-air treatment has been to keep the skin dry while the air is heated all around the limb or part of the body that was subjected to the high temperature. For this purpose, when the temperature to be borne is not very high, the part is simply covered with a Turkish towel; when the whole body is to be subjected, it is covered with an ordinary bath-robe. When temperatures above 300° F. are to be borne, however, the part must be very carefully wrapped up and no spaces allowed to exist between the cloth and the skin. Otherwise, the perspiration at these points will become so heated as to scald the patient.

Precautions.—Machines for giving hot-air treatment are very thoroughly lined with asbestos so as to prevent the patient from being burned. There is no disadvantage in submitting patients suffering from albuminuria or glycosuria to the hot-air treatment. On certain theoretic grounds it has been taught that these conditions constituted a contraindication. In practice they have not proved so. If the hot-air bath is continued too long it acts as a nerve-depressant. In this matter each patient must be a law unto himself. No general rule can be laid down. When the treatment is first given the patient should be specially watched, his temperature and pulse and his general condition faithfully noted, and before any sign of depression manifests itself the treatment should be stopped. Patients grow accustomed to the treatment after a time and then it may be continued for a longer period than at first.

Effects of Hot Air.—When a limb is subjected to hot-air treatment there is at first a lessening, then an increase, in the circulation of the skin of the part, with the injection of the peripheral capillaries and a sense of a warmth. The pulse gradually rises until it is ten to twenty-five beats higher than it was when the treatment was begun. There is a rise of temperature of from one to five degrees. There is usually an increase of respiration up to twenty-two or twenty-four to the minute. A general sense of comfort comes over the patient very soon and continues as long as the treatment is doing good. After a time, which is variable in different patients, a nervous depression supervenes which should not be allowed to continue. As a rule the treatment should stop just short of this and then it will have its maximum effect. Professor Stewart of McGill University says that for rheumatoid arthritis, meaning by this what in the States is known as chronic rheumatism, the hot-air baths are the best remedy there is. They have been tried now in a large number of cases and there is no doubt that they give excellent results in an ailment from which the doctor is able to afford very little relief. For chronic arthritic rheumatism, for muscular rheumatism, for sciatica, for rheumatic painful conditions that succeed old fractures the hot-air treatment is a most important indication.

Possible Contraindications.—It is not positively known whether or not in anemia, fatty degeneration and arteriosclerosis the use of the hot-air treatment is dangerous. The rise of pulse and temperature and a certain tendency to increase of blood-pressure that occurs would seem on theoretic grounds to mean that the hot-air treatment is contraindicated wherever a degenerate heart or arteries are concerned. Although the treatment has been used in a good many of these cases, no accidents have as yet been reported. Special care should be taken, however, with the hot-air treatment in these conditions. The treatments should not be prolonged and the effects of the first few treatments should be noted very carefully.

Dr. H. W. Gibney read a paper, entitled

Rheumatic Joints Treated by Hot Air.—This paper will appear in a subsequent issue of the Medical News.

Electricity in Chronic Rheumatism.—Dr. W. J. Morton said it is the custom to say that very little is known about electricity. Lord Kelvin once said that a good deal more is known about electricity than is known about shoemaker's wax, for instance, or a good many other things that are in common use. It is the custom to divide electricity into the three forms, Faradism, Galvanism and Franklinism. There is, however, no real distinction between these three forms. Electricity in any form consists of the development of electromotive force which, when applied, represents work done.

While, so far as the essential qualities of electricity are concerned, it makes no difference which form of electricity is used, it has been found in practice that the high potential and the high frequency of an influence machine are the most efficient remedial measures.

The form of electricity that Dr. Morton has found most effective for these cases is the static current. One pole of a static machine is connected with the earth, the other is connected with

the patient who is placed on an insulated glass stool. Under these circumstances the patient represents one tin foil of a Leyden jar. The air represents the glass and the room the other tin foil of the jar. The patient is thus subjected to powerful condenser waves, which are most effective in certain painful and trophic conditions. Among the advantages of this form of electrical treatment may be mentioned, first, the fact that there is no sensation of pain or even of discomfort; second, that it produces a benumbing effect upon any painful conditions which may be present; third, that there is no muscular unrest as a result of its application to disturb irritated structures; fourth, that it has been demonstrated that during its application the absorption of oxygen by respiration is distinctly increased and the elimination of carbon dioxide also proportionately increased. There is some loss of weight as the result of the heightened metabolism. This is readily regained, however, because of the tonic effect of the electrical treatment, and the general health improves very materially and rapidly, under frequent administration of this current. In addition to the general effect of the electricity, there is a local reaction which relieves pain and corrects disturbed local metabolic processes.

Nervous Theory of Rheumatism.—Various theories have been advanced for the etiology of the rheumatic condition. For a long time it was thought to be due to hyperacidity of the blood. This view has, however, lost rather than gained adherents of late years. A modern view is that the arthritic symptoms are due to some defects in the nervous system, in a word, that rheumatism is a neurotrophic condition of the joints. This explanation is as good as any other. It constitutes an indication for treatment by electricity that should not be neglected. There is no doubt that for chronic and subacute rheumatism, general electrization is becoming more and more popular and that electrostatic-current methods are especially giving brilliant results of late years.

Technic of Electrical Treatment.—The electrodes may be made of any pliable metal. Dr. Morton uses block tin himself and has it in sheets or rolls that may be cut to any desired size. The spinal electrode for instance may be one inch by twelve inches, and this may be used also to wrap around joints, such as the wrist, or to mold on a limb. The smaller electrode, it must be remembered, the more intense the local electric action. The bare metal should be applied to the bare skin without any intervening leather or other covering. Metallic cloth which can be obtained from military furnishing-stores may be used to wrap a whole limb, or even to envelope the entire person of the patient. A suit consisting of blouse and pajamas may be made from it. If an unpleasant prickling accompanies the application of the current it may be dispelled by pressure. A sitting should last for fifteen to thirty minutes, although this depends to a great extent on the patient. Just as for a ride on a bicycle or on horseback, the condition of the patient should be carefully consulted to determine the length of each treatment.

Results of Treatment.—Immediately following an application of the electrostatic current in painful conditions the most noticeable result is a relief of pain that lasts for some hours. After each cucceeding séance the duration of the relief thus afforded becomes longer and more and more powerful currents may be used with progressively good results. Locally long sparks may be employed with excellent effect in acute painful conditions. Dr. Morton has employed the electrostatic current for twenty years and has found no method so effective for painful conditions that are due to a constitutional diathesis. In gout, for instance, the relief afforded is often so complete and so rapid that the patient stamps after a séance to assure himself that the pain is really gone and that he is not laboring under a delusion. Rheumatoid arthritis may be completely arrested by applications of the electrostatic current. It does not, of course, restore tissue that has been destroyed, but the swelling disappears to a large extent, the disability is greatly lessened, and the patient made very comfortable compared to his former state. Dr. Morton showed by a series of X-ray photographs that even in old cases of rheumatoid arthritis there are often no serious changes in the bony structures. The pathologic conditions in the soft structures are very promptly ameliorated. The first sign that the treatment is doing good is seen in the disappearance of that shining look so characteristic of the disease. After this the joints begin to grow better. There is undoubtedly a fruitful field in hospital work for electrostatics. Every hospital should be supplied with a large influence machine.

Diagnosis vs. Treatment of Rheumatism.—In discussion Dr. Lezinsky said that there would undoubtedly be fewer complaints of failure in the treatment of rheumatism if the diagnosis were made more exactly. Neurologists are constantly finding cases that have been treated for rheumatism in which the painful condition is really due to some nervous defect. There is a tendency in our day to neglect local measures and depend almost entirely on internal medication. It must not be forgotten that the cold pack and local applications, such as wintergreen oil, may be of the greatest service for the relief of pain and may very materially aid the internal treatment. For chronic rheumatism the hot-air treatment is not used as much as it ought to be. The electrostatic treatment has not given much benefit in Dr. Lezinsky's hands. It does good in muscular rheumatism, but does not help chronic rheumatism much, and he is never willing to confine the treatment to static electricity alone. There is no doubt that static electricity would do much more good than it does now in the practitioner's hands, if it were used for a longer period at each sitting. Five to six minutes of an electrical séance can have scarcely more than the psychical influence which so many claim to be the only effect of electricity.

Dr. Manges said that it is undoubtedly a mistake to saturate a patient suffering from rheumatism with the salicylates to the exclusion of local and other forms of treatment. The salicylates are not a specific for rheumatism and they do not prevent heart complications more than any other form of treatment. Dr. Pribram of Prague in his recent work on acute rheumatism in Professor Nothnagel's system of special pathology and therapy collects a large series of cases of rheumatism treated with the salicylates, with 68 per cent. of heart complications, and another series of cases treated without the salicylates with only 50 per cent. of heart complications. At Mt. Sinai Hospital it is noted that patients convalescent from rheumatism suffer to a marked extent from anemia. This must be borne in mind and tonic treatment, especially iron tonics, must be begun as soon as acute symptoms subside. There are two dangers in the use of the hot-air treatment. The one is from fire, which has occurred twice in the wards of the Mt. Sinai Hospital, although the greatest care was taken. The other is the danger of setbacks from exacerbation of symptoms, because of exposure to cold immediately after the hot-air treatment, or because the air of the room is too cold during its administration.

Dr. Kessler said that he has now treated 350 cases of all kinds of arthritic troubles by the hot-air method and he is convinced of the great benefits to be derived from its use. Out of 20 inveterate cases of chronic rheumatism 18 were so much benefited that they were able to resume occupations given up long before. Five resumed work after five years of idleness, one had been helpless for fourteen years. It is not the only treatment used, but it is an excellent adjuvant to other methods. Lactic-acid lemonade seems to be of distinct service in these cases of chronic rheumatism. Joints should not be immobilized during an attack of acute rheumatism as they may become anchylosed. This warning is important as it is mainly the joints that have been immobilized too strictly that come to be treated afterward by hot air. For muscular rheumatism acupuncture is an excellent remedy, and often affords relief when all other means fail. The highest temperature in the hot-air baths should not be above 340° F. There are those who advise the use of 400° F., but the increase of temperature adds considerably to the risk of burns and to the depressing effect on the patient and does not add proportionately to the curative effect of the hot-air bath. At a temperature of 340° F. the apparatus requires the most careful watching to prevent scalds.

Treatment of Neuralgias.—As a rule, neuralgias are not benefited by the hot-air treatment. Besides, there is not infrequently considerable danger in neuralgic cases of the patient taking cold afterward. Sciatica, however, is often relieved by hot-air treatment when everything else has failed. Rheumatic gout is most resistant to treatment. Burns are out of the question, as a rule, in a good apparatus if a reasonable amount of care is taken. The thermometer at the top of a hot-air machine from which the reading is made is always at least 30 degrees higher than the air at the bottom of the machine where a current of fresh air is constantly entering. For neuralgia of the face and for the itching of the eyeballs sometimes noted in gouty subjects, the little machine known as a Japanese hand-warmer often affords a great measure of relief. It may simply be held in the hand and applied to the affected part. Rheumatic iritis, an extremely discomforting condition, is often relieved by the same simple apparatus.

Dr. Satterthwaite, in closing the discussion, said that the hot-air apparatus is not merely a conventional method of treatment, the use of which can be confined to any one who cares to purchase the apparatus. The fact that a notable increase in the temperature, in the pulse, and in the respiration-rate is noted shows that hot-air treatment is a serious therapeutic agent, the abuse of which may be followed by unfortunate results. Hot-air treatment, then, should be given only under the immediate supervision of a medical man and one who has had some experience with this method of treatment and with the apparatus he proposes to use. At present, unfortunately, the use of these apparatus is mainly in the hands of certain non-professionals who do not realize the necessity for care in their use and who probably have no proper notion of the dangers that may be involved in their employment.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held Tuesday, March 6, 1900.

The Vice-President, Joseph Collins, M.D., in the Chair.

Aneurism of Aortic Arch; Pupillary Abnormality.—Dr. W. B. Noyes presented a man, forty-six years of age, who had the initial lesion of syphilis four years ago. He had been referred to Dr. Noyes recently for a recurrent laryngeal paralysis, the result of pressure of an aneurism of the arch of the aorta. Further examination showed increased knee-jerk, mental symptoms, a pupillary abnormality, and a mental dulness which suggested an incipient general paresis. The left pupil was contracted, the knee-jerks were markedly increased; under any mental strain he showed twitching of the face. The case was exhibited to determine whether or not it might not be possible for such an aneurism to cause this pupillary phenomenon by interference with the sympathetic branches. The aneurism is not sufficiently large to involve the spinal cord.

Dr. G. M. Hammond said that he had made a superficial examination of this man. There could be no question about there being certain mental defects, and from a consideration of all the signs and symptoms it seemed to him that the man was suffering from cerebral syphilis. This was am-

ple to account for the change in voice and for the other symptoms.

Dr. Pearce Bailey was disposed to explain the alteration in the voice and the pupil by pressure on the recurrent laryngeal nerve and interference with the sympathetic.

Dr. B. Sachs said that the very great difference in the two radial pulses seems sufficient evidence of the presence of aneurism, and the aphonia is characteristic of peripheral disturbance resulting from solid neoplasm or an aneurism. The condition is entirely typical of what is commonly found in general paresis, cerebrospinal syphilis, and some other conditions. The mental symptoms do not seem to him characteristic of an ordinary general paresis.

Dr. W. M. Leszynsky said that both pupils react very well to convergence, showing that in all probability the pupillary reaction is not dependent upon any special syphilitic condition.

Dr. Noyes said that the examination of the eyes shows mixed astigmatism in both eyes, slight paleness of both optic disks, and weakness of the eye muscles, but no definite paralysis. Laryngoscopic examination shows plainly a recurrent laryngeal paralysis. It has existed about three weeks, and is improving under antisyphilitic treatment.

Specific Cervical Pachymeningitis.—Dr. Sachs presented a man, thirty-eight years of age, who gave a fair history of having had a hemiplegic attack about three years ago. From this he recovered promptly, and had no further trouble until last October, at which time he developed a complete rigidity of the cervicodorsal region of the spine. In addition, he complained of great pain radiating from the lower cervical region into the arm, and presented a very marked atrophy of muscles of the right shoulder girdle. A diagnosis was made of specific pachymeningitis of the cervical region. The case is interesting as presenting a clear example of extraspinal syphilis. The pains and atrophy are interpreted as root symptoms. There is a clear history of syphilitic infection having taken place five years ago. The patient was put upon increasing doses of the iodide, and had taken as much as 60 drops of the saturated solution three times a day. He is now entirely free from pain, and can move his head very freely. The speaker said that in his experience these cases have been extremely rare.

Dr. Joseph Fraenkel said that there is at present a similar case at the Montefiore Home. The patient is a man, about thirty-two years of age, who gave no history of syphilis. He had about four months ago a transient hemiplegia, with some mental deterioration. Six weeks later he developed pain and stiffness in the neck. He was admitted about two weeks ago, and at that time exhibited a marked torticollis. He is stupid and apathetic; the pupils are unequal and do not react to light. There are evidences of the old right-sided hemiplegia, and on the left lateral portion of his neck are two distinct and rather hard tumefactions. The trapezius, deltoid, biceps, triceps, and the interdigital muscles on the left side are all considerably atrophied, and give the reaction of degeneration. All the muscles on the left side of the neck are in a state of increased myotatic irritability. The diagnosis was made of a syphilitic meningitis of the base and of the upper part of the cord. Under antisyphilitic treatment improvement has been quite rapid.

Dr. Joseph Collins thought there could be no doubt that the case just presented is one of those rare examples of syphilitic pachymeningitis, rare in that it attacked the roots. He has seen the case referred to by the last speaker. There had been a true myositis in the cervical region, producing a torticollis, muscular atrophy, and degeneration. He sees no reason for the statement that this case is a parallel to the one presented by Dr. Sachs.

Disease of the Thoracic Division of the Sympathetic Chain.—Dr. Joseph Fraenkel read a paper with this title. He said that most of the textbooks make meager reference to the sympathetic system, and, indeed, there was very little known about the thoracic sympathetic. The following case was reported: The patient, a woman, was first seen on July 25, 1898. Her family history was excellent, and she herself was of simple and temperate habits. She had been in good health up to ten days prior to this first examination. At that time she had awakened at midnight with a peculiar pain in the left extremity, and this had soon been followed by painful contractions of this extremity, and finally of the other lower and upper extremity. The attack had lasted a few minutes and had terminated in a laughing spell. No aura had been detected. The objective findings after an exhaustive examination justified only a diagnosis of hysteria. On April 17, 1899, he found her sick in bed, complaining chiefly of severe pain in the thoracic region. The rhythm of the pulse was greatly disturbed, but otherwise the physical examination was negative. Subsequently there had been a rise of temperature, and auscultation then revealed a distinct systolic murmur over the heart, which was attributed to the great distention of the abdomen with gas and the consequent displacement of the heart. The next morning she was very much better, but the following evening she went into collapse and died before a consultation with a surgeon could be held. At the autopsy, made by Dr. Van Gieson, the four upper sympathetic ganglia on both sides were found buried in a mass of purulent material. The pus lay beneath the pleura near the vertebral column. There were no evidences of recent reactive inflammation in the neighborhood of this abscess. The other findings were negative. Staphylococci and streptococci were found in the pus. There were no tubercle bacilli present. The speaker expressed the opinion that hysteria was the only possible clinical diagnosis in this case, and it should be remembered that fatal hysteria is not unheard of. He had been able to collect fourteen such cases. The case raised the interesting question as to whether the closing symptoms were connected with the earlier ones, or

were entirely independent of them and due to the accidental involvement of the thoracic sympathetic ganglia.

Dr. Hammond said that the report did not seem to him to connect the lesions found at autopsy with the symptoms detailed in the clinical history. The inference was that the patient at first had hysteria and subsequently developed the abscess which caused her death.

Dr. Sachs said he was pleased to learn that there are very few recorded cases of fatal hysteria that could stand a critical examination. He had at one time under his care a woman of twenty-five who presented all possible hysterical phenomena. The diagnosis of hysteria had been made by himself and by others, and was persisted in until the woman had suddenly developed coma. This was followed rather suddenly by anuria and death, and the autopsy revealed chronic nephritis. Of course, the latter had nothing to do with the hysteria. In the case under discussion some of the later symptoms that had been attributed to the hysteria were really the result of the abscess of the pleura. It would seem to him that this abscess must also have involved some of the roots as they emerge from the vertebral column: hence, the symptoms presented could hardly be interpreted as having been entirely the result of an invasion of the sympathetic chain. The case certainly did not present any marked relation between hysteria and the thoracic sympathetic.

Dr. Leszynsky said that hysteria is a functional nervous disorder which occasionally results in organic disease and so indirectly might be the cause of death. It is well for the general practitioner to remember that every symptom observed in an hysterical subject is not necessarily a part of the hysteria.

Dr. Collins took the ground that the first scene presented in this report was one of traumatic hysteria and that the latter symptoms were dependent upon the formation of a subpleural abscess. The woman unquestionably had not had hysteria until after her marriage, yet hysteria, like epilepsy, is a psychosis of early life. The abscess had apparently been of very slow formation, quite circumscribed near the very last, and a very small focus of degeneration could easily have caused her symptoms. The case seemed to show the possibility of the occurrence of hysteria as a part of derangement of the sympathetic.

Dr. Fraenkel said that he had endeavored to report in detail and without prejudice this case, which was clinically hysteria beyond all question. It is generally acknowledged that hysteria may occasionally cause death, usually through some paralysis of the sympathetic. The slight lesion of the sympathetic found at this autopsy would have been undoubtedly overlooked had the pathologist not been put on his guard by the request that a special search be made into the condition of the sympathetic.

Torticollis and Its Treatment.—Dr. W. P. Wilkin reported a case of torticollis occurring in a journalist, thirty-three years old, who had previously enjoyed good health, is of a nervous temperament, and lives liberally. During the summer of 1898 his work was exceptionally arduous, and he then became neurasthenic. After a time he began to suffer from an aching feeling in the back of the neck and along the right sternomastoid muscle. This gradually developed into a marked torticollis. The man entered St. Luke's Hospital in May, 1899, and was made to rest in bed for all but two hours out of the twenty-four, and a support was applied. Various methods of external and internal treatment were tried without benefit. He was then treated by the speaker at the Post-Graduate Hospital by suspension and by the internal use of eighteen-grain doses of the valerianate of zinc. A point of importance in the treatment seemed to be allowing him considerable freedom in the hospital and a liberal diet, and placing him in a private room instead of in a hospital ward. Subsequently the man experienced a great deal of relief while in a London hospital from the use of one grain of exalgin, three times daily. In these spasmodic cases gentle pressure with one or two fingers is often enough to restore the head after it has been drawn violently to one side. One of the best methods of treatment for this variety seemed to be an abundance of rest and a quiet out-door life. The employment of drugs alone can hardly be expected to accomplish much good.

Dr. Collins remarked that he has seen a number of cases of torticollis, but never one so severe and so disabling as this one. It was marvellous to see the prompt improvement that followed the use of suspension.

Dr. Hammond said that a number of years ago he had formulated the hypothesis that clonic torticollis is a result of irritation of the nuclei of the nerves, and that tonic torticollis was the result of irritation of the nerves themselves. Later experience has not led him to change this view, although he is aware that others do not accept this theory. From the history of the case just reported it seemed that this case had at least a partial psychical origin. The beneficial influence of suspension would lead him to suspect a psychical origin, for there is no reason for expecting benefit to follow suspension in a case of organic torticollis. In his own practice he has secured the best results from conium when pushed to its physiological limits. It has often proved serviceable in the organic cases when other remedies failed. In the psychical cases the selection of the remedy is not of much importance unless the psychical impression can be relieved. In the case under discussion he could not help feeling that the means used were entirely inadequate to have accomplished the results unless the case was largely psychical.

Dr. Leszynsky said that he had been intending to report two cases which had come under his care during the past six years, both of which had recovered. One of these patients, a woman, had been kept in bed from two to six months at a time. In addition to the general management so well

understood these patients had received massage and gymnastic manipulations of the head and neck. The first patient had this systematic treatment for a period of nine months. In his case suspension seemed to act both psychically and mechanically. The attendant was instructed to use massage up to the point of thoroughly stretching and exhausting the muscle. In both of these cases he used atropin, conium, and other remedies without much satisfaction. Suspension causes stretching of the muscle, and in this way gives it the needed rest.

Dr. R. G. Wiener said that he has four cases of torticollis which he had been able to observe for a long time. Two of these patients are males with an alcoholic history. By the hypodermic injection directly into the muscle of atropin and morphin, in increasing doses, these patients had been thoroughly restored in nine and eleven weeks respectively. The third case had been treated surgically, but had relapsed. The fourth case had proved rebellious to all treatment.

Curious Hysterical Disturbances of Vision.—Dr. Phillip Meirowitz reported this case, which occurred in a woman of twenty-five, of neurotic temperament and inheritance. In the spring of 1895 she began to suffer from hysterical attacks. Subsequently she developed laughing and crying spells, and these become more frequent and severe. When seen in March, 1898, the seizures had not been so severe and consisted chiefly of crying, brought on by mental strain. Frequently, when gazing into the air, or when looking at the pavement, colored concentric rings would be seen. In darkened corners she would see certain peculiar figures of various colors and shapes. On rising from a couch she frequently saw a succession of blue commas surrounded by green spots. These would disappear on looking out of the window, but people passing in the street would be surrounded by colored borders. Often the images were duplicated, and showed the complementary color. At times her memory became distressingly bad, and the spelling of words became difficult. Her condition had been ameliorated by hypnotism. When first seen in June, 1896, hysterical stigmata had been sought for, but not discovered. Examination of the eyes showed hysterical astigmatism.

Dr. Leszynsky said it is not unusual for the more intelligent hysterical patients to describe a great variety and multiplicity of symptoms. It is difficult to determine how much is purely subjective.

REVIEWS.

The Nervous System and Its Constituent Neurones. Designed for the Use of Practitioners of Medicine and of Students of Medicine and Psychology. By Lewellys F. Barker, M.B., Tor. New York: D. Appleton & Company., 1899.

It may well be said that this work contains everything known up to date of the anatomy of the nervous system based on the neurone conception. It shows a mass of research, an extensive amount of reading, and a fair amount of original work which has developed for the author a high position among the more progressive neuro-anatomists of the day.

After a general introduction showing the evolution of the neurone concept from the early work of Schleiden and Schwann, of Purkinge, and later of Heule and especially of Remak, von Kölliker and Deiters, to the later and more modern discoveries of His, Forel and Golgi, and to the still more recent researches of Ramón y Cajal, von Gehuchten, Retzius and von Lenhossék, the author takes up the most recent work of Apathy which was supposed to have destroyed, if not revolutionized, the entire fabric based on the neurone theory of the organization of the nervous system. He shows that, while recognizing the vast fund of information, of improved technic and of wonderful descriptions given by Apathy to the solution of the complex organization of the nervous system, Apathy's conclusions and deductions must be viewed askance until his work has been compared with the findings of other workers in this field.

The author next takes up the subject of the morphology of the neurones, with its internal and external characteristics and shows the epoch-making work in this field of Nissl, who has laboriously and industriously worked for many years therein. The work of Held on this subject is likewise well described.

The embryology of the nervous system is described under the caption of the histogenetic relations of the neurones. To this subject the author gives much attention and his descriptions and presentation of known facts are thoroughly adequate. Next, the physiology and pathology of the neurone engage his attention, and are followed by the grouping and chaining together of neurones in the complex nervous system of men and the mammals. The last is the main feature of the book and presents all the salient, as well as mooted, points in the anatomy of the nervous system.

Dr. Barker may well be proud of his work, which is without doubt the best presentation of the facts of neuro-anatomy that has appeared in the English language. The publishers have dressed the book in the best style, the illustrations being numerous and many of them finely executed.

A Practical Treatise on Medical Diagnosis for Students and Physicians. By John H. Musser, M.D., Professor of Clinical Medicine in the University of Pennsylvania: Physician to Philadelphia and the Presbyterian Hospitals, etc. Third Edition, Revised and Enlarged. 8vo., 1082 pages. Illustrated. Philadelphia and New York: Lea Brothers & Co. $6.00.

European students have been fortunate in having a number of practical treatises bearing on

medical and surgical diagnosis, but up to 1894 American students had to rely in large part on translations. Those of v. Jacksch and of Vierordt are classics, but each represented different trends in medical diagnosis; the former work leaned distinctly to the laboratory side, while the latter was almost exclusively clinical. The first edition of Musser in 1894 combined within one cover these excellent features and at once gained a popularity which it deservedly enjoys at the present time. This, the third, edition has been almost entirely rewritten and in its present form leaves little for the student or practitioner to desire. In fact there is a danger that the work will become too voluminous and thus defeat its own ends as a ready guide in the methods of diagnosis of diseased conditions. The work is divided naturally into two parts, general diagnosis and special diagnosis. General observations, the data obtained by inquiry and the data obtained by observation are the general subdivisions of twenty-one chapters included in the general portion. In addition to this summary of how to look for symptoms and what is their significance, there are special chapters on the blood and the morbid processes. Part II., dealing with special diagnosis, takes up in turn the methods of examination and the diagnostic features of disease of the following regions: Nose and larynx; diseases of the lungs and pleuræ; diseases of the heart, the blood-vessels and the mediastinum; diseases of the mouth, fauces, pharynx and esophagus; diseases of the stomach, intestines and peritoneum; diseases of the liver, spleen and pancreas; diseases of the kidneys and diseases of the nervous system.

Especial attention should be drawn to the chapter on diseases of the lungs and pleuræ and their excellent illustrations. We know of no work of this type that presents so extended and careful a summary of the important features connected with diseases in this region. The student who knows his Musser cannot fail to do his work well.

Principles of Surgery. By Charles B. Nancrede, A.M., M.D., LL.D., Professor of Surgery and of Clinical Surgery; Emeritus Professor of General and Orthopedic Surgery, Philadelphia Polyclinic, etc. With an appendix by William A. Spitzley, A.B., M.D., Senior Assistant in Surgery, University of Michigan. Illustrated. Philadelphia: W. B. Saunders, 1899.

This book is a reproduction of the thirty-six lectures which are delivered by the author each year at the University of Michigan and cover fairly completely the general principles of surgery without entering into a discussion of regional surgery or operations. Furthermore, the author, recognizing the drift of medical sciences and believing that the time has come when bacteriology and pathology should have their own departments for instruction, has omitted as far as possible a detailed description of the bacterial causes and the pathologic lesions of the various surgical conditions. Considerable space is devoted to a valuable and clear exposition of Nature's so-called "physiologic reaction to injury," or the "process of repair," and especially to the causes, appearances, symptoms and treatment of inflammation. A thorough understanding of the various inflammatory processes is, of course, the basis and foundation of all successful surgery and this question is so well treated that any student or practitioner would obtain many valuable suggestions from a perusal of this volume. Besides these fundamental, practical points, a short but interestingly written appendix sums up the history of the "views concerning inflammation" from the time of Celsus down to the recent days when so much discussion has been advanced, endeavoring to give a clear and logical definition of just what inflammation really is. The chapters on hemorrhage give many valuable suggestions and the description of the surgical diseases, especially hydrophobia, is both thorough and entertaining. As the name of the book implies, the principles of surgery alone are treated of, and the book is, therefore, better adapted for the student or practitioner, who desires knowledge in regard to the causes and the rationale of the treatment of the various surgical conditions, than for the intensely practical man who is always looking for new suggestions with reference to the treatment of special surgical cases. The reputation of the author is sufficient guarantee that this new volume will have a large and well-deserved circulation.

A Manual of the Practice of Medicine. Prepared Especially For Students. By A. A. Stevens, A.M., M.D., Professor of Pathology in the Woman's Medical College of Pennsylvania, etc., etc. Fifth Edition. W. B. Saunders, Philadelphia, 1899.

As the author quotes from Pope in his original preface, "Half our knowledge we must snatch, not take," so does he attempt to put into proper form the knowledge derived from his own wide experience, and place it before the student in order that it may be "snatched," not taken. The little volume is a compendium of all that a student can well be expected to master during his comparatively brief stay at the medical college. The subject matter is placed before the reader succinctly and clearly. The classifications are good, the general arrangement of the various parts of each topic is conducive to clearness, and the fact that the book has now gone through five editions is pretty good evidence that it has met a demand which is as extensive as the contents are intensive. When supplemented and enlarged upon by diligent attendance upon lectures and critical observation at the bedside, the knowledge possible to be gained by the student from this handy little volume can hardly be overestimated. Free use has been made of the works of standard reputation, such as Strümpell, Osler, Vierordt, Gowers, Pepper, Starr, Jacobi, Bruce and Charcot, and the reader may be satisfied that his time

is advantageously spent in the perusal of this well-prepared text-book.

The International Text-Book of Surgery. By American and British Authors. Edited by J. Collins Warren, M.D., LL.D., Professor of Surgery in the Harvard Medical School, Surgeon to the Massachusetts General Hospital; and A. Pearce Gould, M.S., F.R.C.S., Lecturer on Practical Surgery and Teacher of Operative Surgery, Middlesex Hospital Medical School. Volume I. General and Operative Surgery Illustrated. Philadelphia: W. B. Saunders, 1900.

Without purporting to have created anything novel in this text-book, the aim of the authors has been to offer a description replete with the advances of surgery. To this end some of the foremost surgeons of America and England appear as collaborators. The respective chapters are thus worked out by specialists in their particular field. The result is an imposing array of *ex-cathedra* opinions from dogma, as shown in the liberal reference to classical literature and the frequent lengthy quotations therefrom. The principles of surgery embraced in this first volume are before us for detailed consideration. Beginning with bacteriology, we find an unusually extensive rendering of the technics which is decidedly foreign to a manual of surgery. The colored plates of the bacteria are not as good as they might be, and hardly afford an aid to the novice for the identification of the original article.

A lucid and exhaustive exposition of the accepted teachings of inflammation follows in the succeeding chapters, but the like cannot be said of the accompanying crude illustrations which are meaningless without the necessary illustrative notes. The otherwise excellent chapters on septicemia and pyemia would be free from all confusion were it not for the introduction, at the outset, of the article on sapremia, an unknown quantity, which should have been supplementary rather than introductory. In contrast to these slight deficiencies the chapters on the technic of aseptic surgery, fractures and dislocations are of the best and would form a nucleus for a most excellent text-book in each instance. A most impartial chapter is that on anesthesia, and especially the elaborate and extensive consideration given to nitrous oxide is to be commended, although from the pen of a teacher and expert, the chapter on tumors is not creditable in so far as the unusual has usurped the commonplace. Histologic illustrations are deficient, and, quite naturally, photographs of rare clinical cases, lending themselves best for illustrative purposes, abound. The succinct account rendered in the chapter on diseases of the bones is due to the very rational teaching that osteomyelitis is the primary effect. Even this hasty review of this work is convincing of the scholarly application bestowed upon it by its authors, who, as writers, teachers and active surgeons, must necessarily draw attention to this, the latest creation of a text-book on surgery.

THERAPEUTIC HINTS.

For Otalgia.—Examine for the cause, treating nasal, pharyngeal or laryngeal ulcerations where these exist, or having carious teeth drawn or filled. In the acute form prescribe quinine sulphate, gr. ⅓ or ½, three times a day, or antipyrin, grs. xvi at one dose, followed by grs. viii one hour later. Or the following:

℞ Quininæ sulphat. ..... gr. xviii
Potassii iod. ..... gr. xxxvi
Sacch. alb. ..... gr. xlv.
M. Div. in chart. No. vi. M. Sig. One powder twice a day.

For the chronic form order quinine, iodide of potassium, iron, if anemia exists, or Meglin's pills, as follows:

℞ Zinci oxidi 5iiss
Rad. valerian. 5iiss
Ext. hyoscyami alc. ..... 5iiss.
Pulv. et ext. glycyrrh. ..... q. s.
M. Ft. pil. No. C. Sig. One pill daily at first, increasing by one a day up to thirty, then diminishing correspondingly.

External treatment includes morphine ointment, vesicatories, and galvanism, the positive pole to the ear, the negative to the neck. Massage is occasionally beneficial.—*Politzer (Landesmann).*

Inoperable Cervical Cancer.—*Ranoletti* of Rome reports excellent results from applications of formaldehyde in ulcerated conditions of the cervix due to carcinomatous infiltration. The strength of the solution to be used depends on the amount of diseased tissue present and the reaction manifested in individual cases. A 20 per cent. solution is a very strong siccative agent. The infiltrated tissue becomes shriveled up, hemorrhage ceases, and the fetid discharge is suspended, giving the patient great relief. Ranoletti has also tried similar applications in cases of moist gangrene, thereby producing eschars, preventing the absorption of putrid matter which would otherwise occur, and protecting the patient from septic infection. Care must be taken not to allow the solution to touch the healthy tissue.

Pain after Tooth Extraction.—

℞ Spiritus ..... ʒ ss
Chloroformi ..... ʒ i
Arthritis ..... ʒ iii
Camphoræ ..... ʒ ii
Tinct. opii ..... ʒ ss
Ol. caryophylli ..... ♏xv.
M. Sig. Apply on bit of cotton.—*T. B. Welch* (Gorgas, Dental Med.).

Styptic for Bleeding Gums.—

℞ Tinct. krameriæ ..... ʒi
Chloroformi ..... ♏viii
Ac. tannici ..... gr. iv
Menthol ..... gr. iv
Aq. dest. ..... ʒii.
M. Sig. External use.—*Viau.*

THE MEDICAL NEWS.

ORIGINAL ARTICLES.

PAIN AS A PATHOGNOMONIC SYMPTOM OF ECTOPIC PREGNANCY.[1]

BY HENRY C. COE, M.D.,
OF NEW YORK.

IF those who are present were asked to recall the cases which in their experience had given them the greatest anxiety, I have no doubt that the majority would at once think of appendicitis. Considering the uncertainty of the diagnosis in atypical cases, the doubtful prognosis, and the anxious question as to whether an operation should or should not be performed, and when it should be done, acute appendical inflammation is a condition which always renders the practitioner exceedingly uncomfortable. He is fortunate indeed, if among the cases in which life has been saved by an early operation, he does not number others in which either an explorative incision revealed a normal appendix, or far worse, the operation was performed too late to save the patient. In spite of the copious literature on this familiar subject, the fact remains that surgeons of the widest experience can formulate no fixed rules for the guidance of the general practitioner, who after all must rely more or less upon his own judgment in the individual case.

Next to importance as a surgical emergency, although of less frequent occurrence, I would rank ectopic gestation; a condition which has been no less widely discussed than appendicitis, and which presents even more difficult problems from a diagnostic standpoint. Its relative infrequency renders it more likely to be overlooked. The merest tyro is always on the alert for appendical trouble. Every acute pain in the lower abdomen, especially if localized on the right side, awakens his suspicions and leads to a careful investigation. Ectopic gestation, on the other hand, often develops so unexpectedly, is so masked by other pathological conditions within the pelvis, that even the expert is caught napping. A physician in the course of an extended practice may not meet with a case for two or three years, so that he begins to flatter himself that his patients are exempt from this accident, when suddenly it comes like lightning from a clear sky. Old Hebra used to say in his cynical way that "any woman could have syphilis." We shall be more within the bounds of truth if we affirm that "any woman may have an ectopic pregnancy."

It is unnecessary to draw a picture of the classical case presented in the text-books. The student concludes after a single year of practical work that in medicine the exceptions are more numerous than the rules, and this opinion is only confirmed by his experience of ten or twenty years. Nothing would seem to be simpler than the recognition of extra-uterine pregnancy, judging from a review of reports of cases and society-discussions; but every abdominal surgeon must admit that he has frequently met with this condition at the operating-table, where it was entirely unsuspected, or, on the other hand, that he has opened the abdomen in a case which presented almost typical symptoms and has found only diseased adnexa.

An eminent surgeon who long ago passed his tenth century in his list of abdominal sections, recently told me, that after anxiously watching an important case which presented all the symptoms of ectopic pregnancy with impending rupture, and summoning in consultation from a distant city an equally prominent gynecologist who confirmed his diagnosis, he removed the patient to his private hospital, opened the abdomen and —found that the case was one of incomplete abortion, the tubes and ovaries being normal. This confession was most encouraging to me, as I had had a somewhat similar experience in my early days, as others have had.

It is not my intention to discuss the familiar facts regarding the pathology and treatment of ectopic gestation, but to limit myself to a consideration of the single symptom, *pain*. I have been led to call attention to this topic by reason of my experience in a recent case, which seems to be at variance with that of an acute observer, who, in publishing a list of over twenty cases, stated that in nearly every one he had been able to make a correct diagnosis from the characteristic pain *alone*. The following is a brief history of the case:

The patient, a highly nervous young woman, consulted me after she had been married a year, on account of dysmenorrhea and pain in the left ovarian region. Two weeks later I divulsed and curetted a sharply anteflexed uterus, recognizing at the time a prolapsed movable left ovary, not enlarged. I saw little of her until six months later when she came to the office complaining of severe pain in the left side. She had skipped her last period, and a week later began to have an irregular bloody discharge. There were no subjective symptoms of pregnancy. On examination the uterus was found to be somewhat enlarged, and an exceedingly tender mass could be felt behind the left broad ligament. Thinking of the possibility of ectopic gestation, I kept the pa-

[1] Read at a meeting of the Harvard Medical Society, January 27, 1900.

tient in bed for several days under careful observation. The pains persisted and were so severe as to require opiates. Finally, I insisted upon an examination under anesthesia, with a view to positively determining whether the condition was incomplete abortion with a prolapsed ovary or early tubal pregnancy. Dr. G. W. Jarman saw the patient with me, and the removal of decidual membrane with the curette at once settled all doubts. The ovary was somewhat larger than at the time of the former operation, but no enlargement of the tube could be detected. I concluded that the patient had exaggerated her pain, as is so common with neurotic females. During the next five months she enjoyed excellent health, her menstruation being regular and painless. She menstruated last on October 26, 1899, and had intercourse only once or twice afterward, as her husband left the city for a month. Two weeks later she had a sudden attack of pain in the left ovarian region while at a dinner party, but soon recovered and took a short trip out of town. About the time when her November period was due she had, on two or three occasions, transient pains. A week later a grumous discharge appeared and continued at intervals until she consulted me on December 6th. There were no symptoms or signs of pregnancy. The uterus was not enlarged or softened, and on the left side I could still feel what I supposed was a prolapsed ovary—in fact the condition was apparently identical with that of the previous year, except that the pain was more severe.

Absolute rest in bed was insisted on, and the patient was comparatively comfortable for four days (with no variation of the pulse or temperature above normal), when she had another attack of general abdominal pain during the night which was supposed by her to be due to indigestion, consequent upon taking grilled sardines and milk for supper. It was relieved by a codeine suppository. She stated that the pain ceased suddenly. The next morning she was quite lively and comfortable. On making a vaginal examination I noted that there was a distinct enlargement of the mass on the left side, although it still maintained its globular shape and was not adherent. The suspicion of extrauterine pregnancy was strengthened, and with the approval of Dr. E. H. Grandin, whom I called in consultation, she was removed without delay to a private hospital. On the evening of the same day, with the assistance of Dr. Jarman, we made an examination under ether, being prepared to operate if it should seem expedient. After the examination we unanimously reversed our former diagnosis, feeling reasonably certain that the tumor was simply a cystic ovary or a small tubo-ovarian cyst, since it did not appear to be larger than an English walnut, was quite movable, and corresponded perfectly with the body felt by Dr. Jarman and myself at our previous examination. The uterine cavity was not enlarged and was empty.

The relatives were informed of our opinion, and it was at first decided not to operate. Fortunately I yielded to the advice of my colleagues, and with the consent of the patient's husband, decided to make an explorative vaginal section and to remove the left ovary if it was found to be diseased. On opening the cul-de-sac a gush of fluid blood established the diagnosis. Abdominal section was performed without delay and several ounces of blood and recent clots were found in the cavity. An ectopic sac on the left side was easily removed, as there were no adhesions. The site of the hemorrhage was a small opening on the upper surface of the sac, which was very tense and quite thin at the seat of rupture. It would evidently have become enlarged within a few hours, doubtless with a fatal result. The right ovary and tube were normal. After copious irrigation of the cavity with saline solution, a strip of gauze was carried through the vaginal opening and the abdominal wound was closed, the patient having been under ether less than an hour. The convalescence was entirely normal, and the patient was sent home on the twentieth day. She is now, six weeks after the operation, quite well. Menstruation occurred normally two weeks after she left the hospital.

Although several instructive lessons may be drawn from this case, I have cited it merely to illustrate the fact that it would have been impossible to make a diagnosis from the pain alone, which was neither as severe nor as persistent as would have been expected in a case of ruptured ectopic. The patient, who is a woman of more than usual intelligence, insists that it was never colicky in its nature, but resembled rather the throbbing pain of oophoritis or localized peritonitis.

Less fortunate was my experience in another instance in which I watched for a week a patient who had skipped a period, presumably on account of a severe cold which she had contracted at the time, and when the next was due had several attacks of colicky pain in the left side, where I could feel an enlarged tube (I had seen her in consultation two years before on account of tubal trouble). Both her husband and herself strongly denied the possibility of conception, as means had been taken to prevent it. There were no symptoms of pregnancy. I considered the diagnosis of ectopic, but unfortunately delayed operation, waiting for the expected menstruation. A few hours before the time appointed for the operation and while I was talking with the patient, rupture occurred, and although I opened the abdomen an hour later she died before recovery from the anesthetic.

In a similar case, in which Dr. Grandin assisted me, the patient had missed one period and the next one was then due. She had had pain the previous night similar to that which often preceded her menstruation, but was feeling perfectly well when I saw her. There were no symptoms of pregnancy, and as in the former case, there had been no bloody discharge. I

could feel an enlarged tube on the left side and stated to the attending physician my suspicions that the condition might be ectopic and that an early operation might be necessary. He could not believe this possible, as the patient had a history of old disease of the tube, but promised to notify me promptly if the pain returned. She had a second attack the same night, but he did not telephone till the afternoon of the following day, when I found the patient nearly pulseless, with all the evidences of internal hemorrhage. A rapid section was performed, but in spite of all our efforts she died a few minutes after the operation.

In contrast to these cases several others may be cited briefly in which the pains, as well as the other symptoms, were apparently typical, yet the diagnosis of ectopic was erroneous.

Case I.—Multipara without any history of previous pelvic trouble. Two weeks before I saw her she had skipped a period, and soon after began to have severe attacks of colicky pain in the left side attended with faintness and acceleration of the pulse; symptoms which were absent in the cases of ectopic before mentioned. The mass increased in size rapidly, was very tense, and the temperature ranged from 100° to 102° F. I removed the patient to the hospital where she was seen by my colleagues, who entertained no doubt as to the diagnosis of ruptured extra-uterine pregnancy. A large ovarian abscess was found on opening the abdomen, which ruptured during removal, flooding the cavity with stinking pus. She made a good recovery.

Case II.—Multipara, who was sent to Bellevue in an ambulance, suffering from severe colicky pains in the abdomen. There was a distinct history of acute pelvic trouble of two weeks' standing, menstrual irregularity and attacks of faintness, with acceleration of the pulse; the temperature was normal. A mass could be felt in Douglas' pouch which presented all the characteristics of an ectopic sac. The pains were regarded as typical, and my surprise on finding an ovarian abscess was great.

Case III.—Multipara, seen in consultation with a surgeon who had made all his preparations to open the abdomen for ruptured ectopic. The patient had missed a period, had an irregular discharge, and colicky pains on the right side, with attacks of syncope and a rapid, feeble pulse. The uterus was enlarged and a mass could be felt behind the right broad ligament. Exploration of the uterine cavity proved that the case was one of incomplete abortion. I had occasion to curette the uterus again a few months later when the same symptoms were present, and could feel the same mass as before, doubtless a diseased tube and ovary. The patient was exceedingly neurotic and exaggerated her symptoms, a common source of error in these cases.

I watched a case of incomplete abortion attended with severe colicky pains with the greatest anxiety for a week before I was able to decide that a tumor behind the uterus was a prolapsed cystic ovary, and not an extra-uterine pregnancy.

Case IV.—Multipara, who had missed two periods, but without evidence of pregnancy. Severe attacks of abdominal pain with faintness and rapid pulse aroused the suspicion of extra-uterine gestation. A tumor could be felt on the right side. Repeated passage of a sound, and intra-uterine galvanization seemed to demonstrate the impossibility of normal pregnancy. The symptoms became so threatening that an explorative incision was made, when a cystic right ovary was found with pregnancy of eight or ten weeks. Baldy has collected a number of similiar cases in his paper in the *Transactions of the American Gynecological Society*, Vol. XV.

In a case of abdominal pregnancy at term, the history of pain early in the pregnancy, but not afterward, was so vague that not the slightest suspicion of the true condition was entertained. It was supposed to be hydramnios, until after the lapse of ten months the unusual size of the abdomen, and progressive emaciation of the patient led to the inference that she was suffering from an ovarian cyst or cancerous ascites. She made a good recovery, after removal of the fetus and placenta.

In order to grasp the significance of the symptom *pain* in connection with tubal pregnancy, it is necessary to follow the pathological changes which occur in the tube from the time of impregnation until the final rupture occurs. These will vary according to the location of the ovum and the fact whether the tube is free or has been fixed by preëxisting adhesions. If impregnation occurs near the fimbriated extremity, the product of conception may be expelled into the peritoneal cavity at an early stage, with slight hemorrhage, and an encysted blood-clot formed. At the time of the accident the pain may be comparatively slight and transient, while the symptoms due to the resulting localized peritonitis so mask the original condition that it is apt to be entirely lost sight of. These are the cases which are so often diagnosticated as diseases of the adnexa, the error being discovered at the operating-table. The same comment applies to cases of hemorrhage into the tube and so-called tubal mole, formerly designated by the "meaningless term, haematosalpinx," as Sutton aptly puts it. Here the distention of the tube is so gradual that the characteristic colicky pains may be entirely absent.

In a typical ectopic pregnancy occurring in the middle of the tube the pains previous to rupture may be due to various causes. Doubtless slight uterine contractions occur from time to time during the first weeks, which closely simulate those noted in cases of suppressed menstruation due to sudden cold. This would easily lead to error as in one or two of the cases which I have cited. The exact cause of these contractions is not clear; in some instances in which the patient has an anteflexion with stenosis they are undoubtedly due to the expulsion of clots as in ordinary cases

of obstructive dysmenorrhea. It is fair to assume that the stretching of the muscular wall of the tube due to the growth of the ovum would give rise to sudden pains, often of a spasmodic or colicky nature. These would hardly in themselves be pathognomonic of ectopic gestation since they have also been noted in connection with tubal disease, the so-called "*colica scortarum.*"

In cases in which the tube has been fixed by old adhesions, these pains would naturally be more severe, and in connection with a previous history of irregular menstruation and localized peritonitis, the presence of an enlarged tube would render the diagnosis of early ectopic gestation exceedingly difficult.

Several explanations have been given of the preliminary attacks of pain observed in a typical case of tubal pregnancy. Lawson Tait always insisted that each attack represented a slight rupture, with the escape of a small amount of blood, and claimed that he was able to demonstrate at the operating-table the presence of blood-clots of different ages, each corresponding to one of the slight ruptures. While it is true that old and recent clots, as well as fluid blood, are often found on opening the abdomen, the first case which I reported shows that although there were several distinct attacks of pain, the rupture, slight as it was, could hardly have occurred before the night previous to the operation. In several of the cases of encysted rupture upon which I have operated, it seemed probable that, in spite of several attacks of pain, it was only on one occasion that blood actually escaped into the peritoneal cavity.

Janvrin's explanation (*Trans. Amer. Gyn. Soc.,* Vol. XIII.) has always seemed to me more satisfactory, *viz.,* that the preliminary pains are due rather to the rupture of small blood-vessels in the wall of the sac, or to the stretching or tearing of nerve filaments. He lays great stress upon the importance of these slight attacks in connection with the cessation of menstruation and a bloody discharge, and the presence of a tumor, as pathognomonic of unruptured tubal pregnancy, and as a strong indication for the primary operation. As to the possibility of diagnosticating this condition before rupture, I have no hesitation in affirming that it may be done, in spite of the fact that Bland Sutton in his "Diseases of the Tubes and Ovaries" states positively that only one authentic case, that of Herman, is on record. I personally assisted Dr. J. S. Hawley in an operation in which he removed an unruptured ectopic sac, previously diagnosticated as such, and Kelly has reported a similar one. However, I believe that these cases are extremely rare, and, as Tait claimed, they are usually recognized only after rupture has occurred.

Another source of pain in connection with ectopic is not always recognized by those who regard this symptom as pathognomonic; I refer to the localized peritonitis which attends pelvic hematocele, resulting in the formation of adhesions that shut off blood-clot from the general cavity. This condition in itself causes not only more or less aching pain on the affected side, but often paroxysmal attacks which are the frequent accompaniment of pelvic inflammation. This peritonitis may so mask the original condition that the diagnosis is made only after the abdomen has been opened. (In this connection a specimen of ruptured ectopic complicated with a parasitic uterine fibroid was shown. See *Trans. N.Y. Obstet. Soc.,* Jan., 1900.)

It is well known that neoplasms of the corresponding or opposite ovary, pyosalpinx, hemato- or hydro-salpinx of the opposite tube, are often found in connection with tubal gestation. These conditions give rise to pain which may be readily mistaken for the more acute condition. Thus, in the first case reported disease of the ovary had long been present, giving rise to symptoms which on a previous occasion were thought to be due to ectopic gestation. Even in cases of intraperitoneal rupture with profuse hemorrhage the symptoms may simulate other conditions.

I reported a case several years ago in which a physician was called to see a young woman who had been married only six months. She had eaten a quantity of cherries the previous evening and had an attack of vomiting and diarrhea, with general colicky pains in the abdomen, which differed in no respect from those attending an ordinary enteritis. Although he had never seen a case of extra-uterine pregnancy, the fact that the patient had missed a period without symptoms of pregnancy, led him to make an examination and he found a mass in Douglas' pouch. He telephoned for me at 2 o'clock in the morning from a neighboring town. In company with Dr. Jarman I took an early train, prepared to operate. When we arrived the patient was entirely free from pain, with normal pulse and temperature, presenting no evidence of internal hemorrhage. After some discussion we decided to make an exploratory incision. We found a typical ruptured ectopic, with at least a pint of fluid blood and recent clots in the cavity. Doubtless the immediate cause of rupture in this case, the patient having had absolutely no symptoms previously, was the straining during the attack of diarrhea and vomiting. The occurrence of rupture in connection with straining at stool, violent muscular efforts, etc., may easily lead the unwary attendant to attribute the pain rather to the inciting cause than to the true condition.

I have noted in two of the cases mentioned that the rupture occurred at the time when the next menstrual period was due, doubtless attributable to the increased pelvic congestion, so that the pain was referred both by the patient and physician to the uterine colic, which is common under the circumstances. In neurotic patients, or in those who commonly exaggerate their pain, the diagnosis is often extremely difficult, in fact, I believe that it is in this class of cases that errors are most often made. It is difficult, especially

for one who sees a patient for the first time, to decide regarding the severity and location of the pain. As you know, many women with a prolapsed ovary will complain more bitterly than others with the most serious disease of the adnexa.

I reported a remarkable case of double tubal gestation in a woman who came to my office from Brooklyn, giving a history of severe abdominal pain two or three days before, while straining at stool. She was in such good condition when I examined her, and so free from pain that I could hardly believe it possible that rupture had occurred, yet on opening the abdomen two days later, expecting to find a dermoid cyst which my colleagues and myself had diagnosticated, I found not only a live fetus with a large quantity of fluid blood, old and recent clots, but a second ectopic in the same tube, which from a careful history that I obtained afterward must have been of ten years' standing.

To mention the various conditions which have been mistaken for ruptured ectopic would be to give a formidable list. Among them appendicitis and torsion of the pedicle of a small ovarian cyst are most common. The symptoms may be almost identical as regards the sudden occurrence of pain, its localization, and the presence of a tumor on examination. If in connection with this there is a history of menstrual irregularity and vague symptoms of pregnancy, it is difficult to see how an error can invariably be avoided. At the last meeting of the Obstetrical Society Dr. Barrows presented a ruptured ectopic sac, removed through a lateral incision in which the history and location of the tumor corresponded perfectly to appendicitis. When we recall the not infrequent cases in which a diseased appendix is found adherent to an ectopic sac, it is easy to see how difficult is the differential diagnosis.

To summarize: Pain alone, when not accompanied by a clear history of menstrual irregularity, symptoms of pregnancy, and the presence of a tumor at the side of the uterus or in Douglas' pouch, known to be of recent development, is pathognomonic of extra-uterine pregnancy only under certain conditions, *viz.:* The pain is of a sharp colicky character, distinctly localized on one side, attended with faintness more or less marked, and is usually followed by intervals of hours or days of complete remission. The pulse is accelerated during the attack, but there is no rise of temperature. The latter is an important symptom distinguishing ectopic from inflammatory conditions. The violent tearing pain attending intraperitoneal rupture is accompanied by the unmistakable evidences of internal hemorrhage. In extraperitoneal rupture the symptoms vary in severity according to the amount of blood lost, but soon subside, being succeeded by the usual evidences of pressure resulting from a mass in the folds of the broad ligament which displaces the pelvic organs. A persistent pain following the acute attack may indicate localized peritonitis.

TUBERCULOUS DISEASE OF THE URINARY APPARATUS.

By J. M. GILE, M.D.,
of Hanover, N. H.

Tubercular disease of the urinary apparatus hardly appears to receive in our text-books the amount of attention that its frequency and seriousness might fairly demand.

Medical authorities appear to be somewhat at variance, too, in their opinions on the disease, particularly on the question of prognosis. One text will give the impression that at worst its course will be slow, with probability of longer or shorter periods of quiescence with entire absence of symptoms; while another advises you to expect a speedily fatal termination. I have heard a surgeon of wide reputation and unquestioned experience, when told that a patient had suffered for eighteen months with tuberculosis of the bladder, remark that there must have been a mistake in diagnosis or the patient would surely have been dead, instead of enjoying, as he was, fairly good health.

My own observation leads me to believe that the disease, when it attacks the urinary organs, acts precisely as it does in any other part of the body, and hence we may expect constant and wide variations in its course. Tuberculosis of a bone or joint may in one case spread rapidly and widely, eventuating in a general process that causes early death; another case may progress so slowly that by natural processes the diseased tissue is circumscribed and imprisoned, so that for years or even a lifetime it gives no symptoms. A case of pulmonary tuberculosis may bring its victim to the grave within two months of the time of invasion; while on the other hand the records of post-mortem rooms would appear to show that from twenty-five to fifty per cent. of the whole human race are at some time in their lives infected with this form of the disease, which either becomes entirely cured, or, as in the previous instance, imprisoned and harmless.

Illustrative cases of these two extremes in the progress of the disease may be of interest. We must, however, preface these cases with the admission that it may make a marked difference in the result, whether it is a kidney or the bladder that is affected; also, that it may, in many cases, be difficult to determine positively which is the affected organ.

Case I.—One of a rapidly fatal type, was in a young woman of twenty years, a school teacher by occupation, and with a record of good health. The only tuberculosis in the family appeared to be in the case of a maternal uncle who died of pulmonary tuberculosis. A rather curious coincidence in the family history is that the father and mother both died of typhoid fever, the deaths occurring far apart, both in point of time and place; one brother had the same disease, and the case in question is reported to have had it coincidently with the onset of the tuberculous trouble.

On November 1, 1898, this patient began to

feel pain in the right side and back over and through the region of the kidney. November 7th typhoid symptoms had developed and the patient ran an apparently typical course of the disease; recovery, however, was not satisfactory, and the difficulty in the region of the right kidney became more prominent. Early in January a tumor could be determined through the abdominal wall, and examination of the urine showed pus, albumin, and tubercle bacilli. The patient was again failing, was much emaciated, and an early fatal result was clearly to be expected. She was admitted to the hospital January 18th, with a distinct tumor, which elevated the wall of the abdomen in the front lumbar region. An operation proved this tumor to be a kidney which was hardly more than a shell distended with pus and tuberculous material. The patient lived less than a week after the operation, making the entire period of illness, from the appearance of the first symptom, a little less than three months. Of course, it may be said that operation here interfered with the natural course of the disease, but I think that any one who had seen the case just before operation would have felt that it did not materially hasten the result.

Case II.—This case, illustrative of the slower course of the disease, is now under my observation. The patient is a female, of about twenty-two years of age. Her mother died of tuberculosis of the lungs: as a child, the glands in her neck enlarged, suppurated, and discharged. Her general health, however, was of the best until three years ago last fall, when she had an attack of peritonitis that kept her confined to bed nearly all the following winter. I did not see the case at that time, but the history is that there was rather high fever, complete loss of appetite, great abdominal distention and excessive abdominal pain. The physician in charge considered it a case of tuberculous peritonitis, and, from the special pain and tenderness referred to the region of the left ovary, believed this to be the primary focus from which the disease had spread.

During this illness, however, symptoms of great irritability of the bladder made their appearance; also much pain referred to the region of the kidneys. Definitely, what the examination of the urine showed at this time, I do not know. In May, following the onset of the attack in November, the patient began to improve and made a rapid recovery. The only symptoms left were recurring attacks of irritable bladder, causing frequent and painful urination and pain in the back. Two years later the patient was married and I first saw her last July when having one of the bladder attacks. She was to start for a month at the seashore the next day. She was given some buchu and a sample of urine was secured. The examination of this latter was a surprise to me, for although there was very little pus present, it yielded fully one-fourth of one per cent. albumin. The specimen was small, and, as most of it was used in chemical tests, no examination for tubercle bacilli was made. The patient had left town and I simply notified her that I found the condition such that I thought she should put herself under the care of a physician wherever she might be that summer. I saw no more of the case until November, when I was called on account of a miscarriage. This went on normally and the patient did well for one week afterward; then pain began in the region of left ovary and great tenderness developed on palpation. Abdominal distention became excessive and the patient showed the characteristic signs of an indolent tuberculous peritonitis. Examination of the urine now, as before, showed a large quantity of albumin, and staining of the centrifuged sediment for tubercle bacilli showed them to be present in large numbers. As I was anxious to have all the information that could be secured in this particular case, Dr. Kingsford carried it through a guinea-pig for me and produced a pure tuberculous infection. The quantity of albumin present, the pain in the back, which now had become a marked feature of the case, and the pelvic and renal epithelium present, clearly prove, I think, that the process affects the kidney as well as the bladder. Believing, however, that the ovary was the seat of primary trouble as far as the abdomen was concerned, I recommended operation for removal. This advice was not acted on, however, until March last, after the patient had spent the winter in bed, constantly suffering pain, with the kidney symptoms constantly in evidence, but of variable intensity. March 9th I operated and found a double hydrosalpinx, the tubes evidently permanently occluded, the walls tense and thin and the fimbriæ sealed down and obliterated. Both tubes with the ovaries were removed. The patient made a good recovery from the operation; she is completely relieved of the pain in the ovarian region, but there is still a variable amount of distention. She is up and out of doors daily and making steady progress, but bladder and kidney symptoms are still in evidence.

This patient, then, despite hereditary tendency to the disease, despite tuberculous complications elsewhere in the system, and despite the shock of operation, has resisted the progress of the disease in the kidney for over three years, and still bids fair to be comfortable for an indefinite period to come. I could multiply from my own experience instances as striking as these of the variable course of the disease, but these are sufficient and are typical, not exceptional.

The discussion of the diagnosis of the disease deserves careful study. I am satisfied that it exists far more frequently than it is diagnosticated. The only absolutely pathognomonic indication of its existence is the presence of tubercle bacilli in the urine. Although the discovery of the organisms in excretions and solid tissues has been considered a matter of difficulty and even uncertainty, the modern investigator with improved methods of staining and section-cutting, and with the aid of the centrifuge and live animal cultures, can discover them, if present, with certainty.

The use of these aids to diagnosis cannot be too strongly urged in any obscure case, or in any case in which some other cause for an existing abnormality of the urinary organs is not perfectly apparent. Particularly in tuberculosis of the bladder, I know of nothing else to differentiate it from a cystitis from other causes. And more and more, with the aid of bacteriology, we are making our diagnosis from the positive, rather than the negative, evidence of exclusion.

Perhaps this difficulty of differential diagnosis applies most often to the disease when affecting the bladder. As an aid to this diagnosis, it has been claimed that a tuberculous cystitis causes a more albuminous urine than does cystitis from other causes, but careful examination of a sufficiently large number of cases of cystitis will, I think, convince any one that the albumin is in proportion to the amount of pus and blood present, and that when much albumin is found with little pus it is pretty certain evidence of the extension of the disease to the pelvis and probably to the parenchyma of the kidney.

The difficulty of this diagnosis of bladder tuberculosis was illustrated in the case of a medical student who came under my observation two years ago.

Case III.—A man of twenty-six or twenty-seven years of age, an athlete, always in the best of health and of exemplary habits, began to have some irritability of the bladder causing frequent desire to void urine. He took simple treatment, sometimes local, sometimes internal, securing some temporary relief, but no permanent improvement. One day, while listening to a lecture on cystitis, it occurred to him that this was a tuberculous affection, and having a sample of urine examined with this in view, bacilli were readily found. This has been one of the cases of slow progress; since the onset of the disease, the man has done over two years of hard work as a medical student, received his degree, and has now gone to Colorado in a very good condition of health, with the intention of there practising his profession. This, again, I believe to be a typical case as illustrating the difficulty of making complete diagnosis, if one omits the test for tubercle bacilli, and I have no doubt that many of us have on hand cases of chronic cystitis that depend on tuberculous infection.

The cases, however, that may give us difficulty in diagnosis are by no means confined to those affecting the bladder. A tuberculous kidney may offer a considerable variety of symptoms. The condition with which it is most liable to be confused, perhaps, is renal calculus. We have already referred to the pain that is present in the kidney cases. This appears to be a very constant factor, but is rather variable in its character. Although usually described as dull or heavy, it often becomes sharp, cutting, or even spasmodic, and while usually constant, it may be, and indeed often is, intermittent and paroxysmal. In location, it is generally confined to the region of the affected kidney, yet it may shoot down the course of the ureter and into the testicle. The pelvis of the kidney is pretty certainly involved in the process with the production of more or less suppurative pyelitis; from this chills, fever and the general symptoms of a pus-infection ensue, precisely similar to the condition produced by a pyelitis resulting from an impacted calculus.

Case IV.—A case illustrating this difficulty in diagnosis, was admitted to the Mary Hitchcock Hospital in Hanover in January, 1898. The patient, a man twenty-six years old, of previous good health, but of tuberculous family, had the previous July a severe attack of pain in the left groin, that began in the morning and continued until four o'clock in the afternoon. The pain came on suddenly, was of extreme severity, was accompanied by frequent and painful micturition and followed by chills. These attacks were repeated as often as once a week until the following December, blood being passed during some of the attacks. Up to this time the patient's appetite and general health remained fairly good. But his condition then began to fail, evidence of septic infection appeared, and the pain in the left groin became more constant. Admitted to the hospital in this condition in January, the urine loaded with pus, a diagnosis was made of impacted renal calculus with resulting pyelitis. The condition of the patient was so poor, and failure had recently been so rapid, that radical operation was considered necessary. Lumbar incision was made and no stone found, but, on the other hand, a large suppurating tuberculous kidney. All the symptoms seemed to point so definitely to renal calculus that no one who saw the case deemed it necessary to look for anything farther. Of course, it is possible that his earlier attacks may have been due to passing calculi, but positive evidence of this never appeared in the passage of the same through the urethra, and the later symptoms of impacted stone were certainly due to the tuberculous process. Such experiences make me more and more inclined to have sediment examined for tubercle bacilli in all urinary cases.

There is one thing, however, that the discovery of the bacilli in the urine does not do, that is, to definitely locate the disease in a particular part of the urinary tract; whether the disease be in the kidney, ureter, bladder, or testicle. The simple finding of the bacilli in the urine indicates nothing. We must add to this the subjective symptoms as indicating cystitis in the bladder case, or, the loin pains, when the affection is of the kidney, also careful microscopical examination of sediment to determine from what point cell elements are being desquamated so rapidly as to indicate pathological processes.

When one of these organs has become involved the others are pretty sure to do so sooner or later. As to what organ is most likely to be the seat of primary affection appears to be simply a question of circumstance, that is, something has happened to render the organ non-resistant, or it has been especially exposed to infection.

The claim that it always originates in the kid-

ney and extends to the bladder only by having the bacilli carried down with the urine is without foundation. Many bladder cases are certainly primary, and the disease extends from this organ to the kidneys by contiguous tissue apparently quite as certainly as, although perhaps more slowly than, in the other direction.

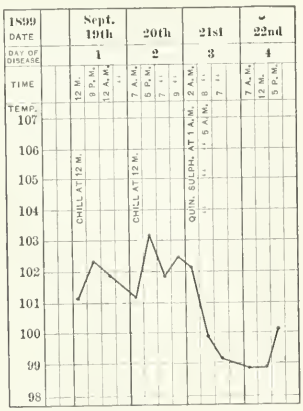
Briefly, then to conclude: The condition is one of considerable frequency, greater, probably, than the number of cases diagnosticated would indicate. Its course is quite as variable as that of the same disease when affecting other organs and may prove rapidly fatal or run a very indolent course. For certain diagnosis we must depend on the bacteriologist, but even this will not definitely localize the trouble. The hereditary character of the disease appears to be even more definitely marked than in pulmonary tuberculosis. The age incidence, from the record of my own cases, is markedly in young adult life, rather than in the middle age as frequently stated, while the location of the disease is merely a matter of circumstance and follows no fixed rule.

A CASE OF PROBABLE ACCIDENTAL INOCULATION WITH THE MALARIAL PARASITE.[1]

By WILLIAM H. KATZENBACH, M.D.,
OF NEW YORK;
PROFESSOR OF GENERAL MEDICINE IN THE NEW YORK POLYCLINIC.

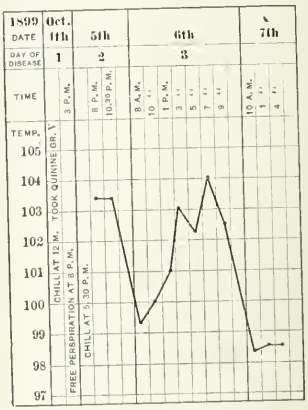
SEPTEMBER 18, 1899, Dr. X. performed a vaginal hysterectomy upon Mrs. W. On the following day, September 19th, at noon, Mrs. W. complained of chilly sensations and her temperature

FIG. 1.



rose to 101.2° F. At 9 P. M. the temperature was 102.4° F.; at midnight, 101° F. September 20th, 7 A. M., the temperature was 101.6° F. At noon she had a chill lasting about half an hour. At 5 P. M. the temperature was 103.2° F.; 7 P. M., 101.8° F.; 9 P. M., 102.4°F. September 21st, 1 A. M., the patient was given five grains of quinine sulphate. At 2 A. M. the temperature was 102.2° F.; at 6 A. M., it was 99.8° F., and an-

FIG. 2.



other five grains of quinine sulphate was administered. The quinine was continued in five-grain doses morning and evening. September 22d, 7 A. M., temperature, 98.8° F.; 5 P. M., 100.2° F. The patient ran a little temperature in the afternoon for several days. This varied from 99° F. to 100.2° F. (See Chart I.)

October 4th, Dr. X. had a chill at noon lasting half an hour. He took five grains of quinine sulphate at its beginning. At 3 P. M. his temperature was 103° F. At 8 P. M. there was a copious perspiration. October 5th he felt well, ate a good breakfast, attended to work during the day, but went to bed at 5 P. M. At 5:30 P. M. he began to yawn and feel chilly, and took five grains of quinine. At 8 P. M. the temperature was 103.4° F.; it was 103.4° F. at 10 P. M., at which time he was seen by the writer.

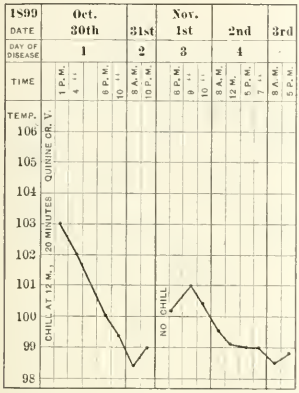
Physical examination failed to reveal any evidence of local disease. The spleen was palpable. Malarial infection was suggested as the condition, and a blood-examination was recommended. At this time Dr. X. recalled the circumstances of Mrs. W.'s attack, which yielded to quinine, and also the fact that several times during the operation he had pricked his finger with the needle he was using. Quinine was ordered.

October 6th at 8 A. M. the temperature was 99.4° F.; 10 A. M., 100° F.; 1 P. M., 101° F.; 3 P. M., 103° F.; 7 P. M., 104 F°. There was not any chill this day. October 7th, at 10 A. M., the temperature was 98.4° F.; 1 P. M., 98.5° F.; 4 P. M., 98.5° F. (See Chart II.) He continued the use of quinine for several days and remained well until October 30th, noon, when he had a chill lasting twenty minutes, during which he took five grains of quinine. At 1 P. M. the tem-

[1] Reported at the meeting of the New York Clinical Society, December 22, 1899.

perature was 103° F.; 4 P. M., 102° F.; 6 P. M., 100° F.; 10 P. M., 99.5° F. October 3d, 8 A. M., temperature 98.4° F.; 10 P. M., 99° F. November 1st, the morning temperature was not taken; at 6 P. M. it was 100.4° F.; 9 P. M., 101° F.; 10 P. M., 100.6° F. November 2d, 8 A. M.,

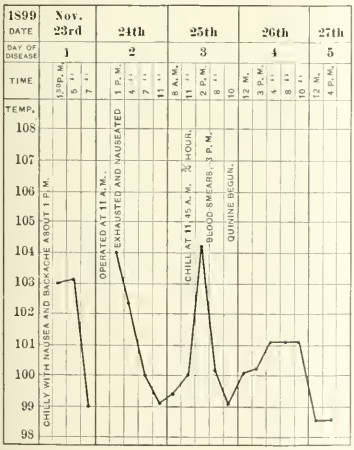
Fig. 3.



99.6° F.; 12 M., 99.2° F.; 5 P. M., 99° F.; 7 P. M., 99° F. (See Chart III.) During this attack he took quinine for several days, but was not seen by the writer.

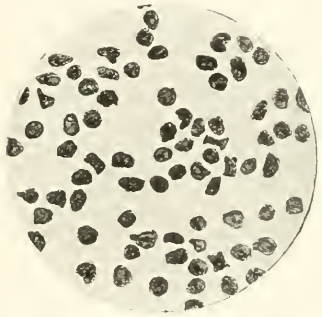
November 23d, at 1 P. M., he "began to feel a little nausea and backache, and a creepy feeling

Fig. 4.



came on." At 1.30 P. M. the temperature was 103° F.; at 5 P. M. it was 103.2° F. He had severe headache. The spleen was distinctly palpable. Evidence of local disease was not present. He was urged to have a blood-examination made, and, pending this, he was requested to take no quinine. At 7 P. M., after an alcohol rub, his temperature was 99° F. Calomel was given at night to be followed by a Seidlitz powder in the morning. November 24th he felt well enough to go out, and operated on a patient from 11 to 12:30, after which he felt exhausted and nauseated. At 1 P. M. his temperature was 104° F. At 3 P. M. blood-smears were taken by Dr. Jeffries. He went home and to bed at 4 P. M. with a temperature of 102.4° F. At this time there were not any local symptoms present. He was given an alcohol rub. At 7 P. M. the temperature was 100° F.; 11 P. M., 99.2° F. November 25th, 8 A. M., temperature, 99.4° F. At 9 A. M. he received a report of the result of the blood-examination, showing that the malarial parasite was present, and he immediately took Warburg's tincture. At 11:45 A. M. he had a chill which lasted until 12:30 P. M. At 2 P. M. the temperature was 104° F.; 6 P. M., 100.2° F.; 10 P. M., 99.2° F. At 9:30 he had taken five grains of quinine sulphate and during the night

Fig. 5.



Normal and infected corpuscles as they appeared magnified 540 diameters.

he took ten grains more in divided doses. November 26th, he did not have any chill. At noon his temperature was 100.1° F.; 4 P. M., 101.2° F.; 8 P. M., 101.2° F.; 10 P. M., 101.2° F. November 27, 7 A. M., he took five grains of quinine, and at 9 A. M. he was given an alcohol rub. At 11 A. M. temperature was 98.5°F.; 4 P. M., 98.5° F. Quinine has been continued in small doses, on account of easily produced cinchonism, up to the present date with no return of fever. (See Chart IV.)

Mrs. W. has always lived in a malarious district in North Carolina. Her physician writes, December 7, 1899, to Dr. X.: "She had a few chills daily last December, but took quinine and has had no return until with you after the operation. She has had none since, unless it be a very slight one November 1st, which she followed with quinine and has had no return of symptoms. She says about eight years ago she began to have quotidian chills almost regularly for a period of four years, then had none until last year, as above

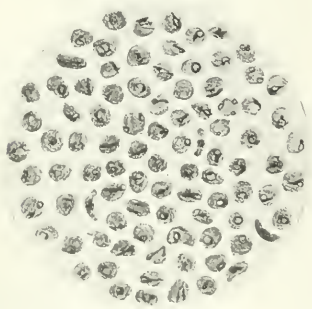
mentioned. I have not had any blood-examination made."

Dr. X. had two attacks of chills and fever in 1866, while living in Wisconsin, during a period of from four to six weeks, each lasting about a week. He has been a resident of New York for twenty years. He was at Seabright, N. J., from July 3d to 20th, this past summer, and in New Hampshire from July 25th to September 15th.

The following was received from Dr. Jeffries: "As per request, I called upon the doctor November 24th to take a sample of his blood for examination. I found him in his office with a temperature of 104°F. A number of smears were made from the peripheral circulation, and immediately taken to the laboratory for examination. Stained with eosin and methylene blue, a great number of malarial parasites of the estivo-autumnal variety were observed. It is rare, indeed, that I have seen malarial blood with so great a number of corpuscles acting as hosts to this parasite. It is quite difficult to find a field with a $^1/_{12}$ inch objective that does not contain several of them. They are of the variety represented in the drawings accompanying this report. As you can see, it is of the particular type of estivo-autumnal considered by some as a distinctive class, which they call quotidian."

The malarial parasite has never been found in the air or soil or water of a malarial district. It has been supposed that malarial infection takes place through the respiratory or digestive tract, or by the skin from insect bites. (Thayer.) But efforts to infect by means of inhalation of dried and powdered blood containing the parasite have not been successful; and failure has invariably attended the ingestion of water from marshes in malarial regions, and of blood from infected individuals. Inoculation has been produced over

FIG. 6.

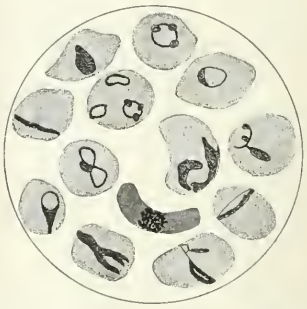


Invaded corpuscles from one slide demonstrating the multiplicity of involvement.

and over again by intravenous and subcutaneous injection of blood containing the living malarial parasite, and "the type of the fever and that of the parasite in the inoculated individual are always the same as in the patient from whom the blood is taken." That mosquitoes, or, to be more precise, certain species of the mosquito, are the carriers of the infection is a theory which is increasing in favor, and facts are accumulating to warrant and strengthen this theory.

The experiments of Ross, of the numerous Italian observers, of Koch, and of others, with

FIG. 7.



A portion of Fig. 6, enlarged *2000* diameters.

the Anopheles are familiar to those who are interested in the study of malaria. Their conclusions are that the Anopheles is the extracorporal host of the malarial parasite. Every recent writer refers to the results of Theobald Smith, who demonstrated that the cattle-tick conveys the Texas cattle-fever from one animal to another, and from this argues the possibility of the conveyance of the malarial parasite to man by the mosquito.

Manson believes that "the quartan, the tertian, the estivo-autumnal parasite, each has its special species of mosquito as its special extracorpuscular host; that the malaria parasite inhabits man when it gets the chance; that it can pass from man to the mosquito, and that it can pass from mosquito to man." Celli says that malaria is an "inoculation disease."

In the light of the above it is not difficult to conceive that Dr. X. was inoculated by the needle while operating on a patient in whose blood at the time of the operation a group of parasites was passing through its cycle of development, for within twenty-four hours she had her first paroxysm. Only a few days before the operation she had come from North Carolina—a section of our country where the estivo-autumnal type of the parasite prevails. This form of parasite is not found in the blood of patients infected in the ordinary way in the vicinity of Manhattan. Dr. X. had not, so far as he knows, been exposed to malarial influences for years. When he returned to the city from his vacation on September 15th he considered himself in robust health.

Jewish Hospitals.—The proceeds of the Hebrew Charity Ball, held in Philadelphia February 20th, were $10,656. This amount has been distributed among the various Jewish hospitals and homes in the city.

THE CURABILITY AND TREATMENT OF EARLY PHTHISIS.[1]

By W. F. HAZELTON, M.D.,
OF SPRINGFIELD, VT.

Over a decade ago, while an interne in Bellevue Hospital, the writer's attention was directed to some cases of pulmonary tuberculosis which had undergone arrest and cure and which were retained as pensioners of the hospital. The late Dr. Austin Flint was in the habit of showing them in his clinic as illustrations of what he termed "the self-limitation" of that disease. Although pathology had been teaching that healed areas of tuberculosis of the lung were not uncommon, yet the knowledge was sufficiently rare to occasion surprise at clinical demonstrations of its truth. At the end of my term of service as interne I spent over a year in the Adirondack Mountains and in Colorado, seeing many cases of phthisis in both regions, when I was again still more impressed by the considerable number who actually got well. Believing, then, that pulmonary tuberculosis in its early stages is susceptible of arrest and cure, I have undertaken to bring together a few of the observations which have been made during the past decade which tend to substantiate this belief.

In 1889, Vibert,[1] examining the register of necropsies of the Paris morgue, was struck by the fact that in 131 individuals of from twenty-five to fifty-five years of age, having all succumbed to violent or sudden death, it was noted that the existence of pulmonary tuberculosis was recognized in 25; in 17 of whom the malady was in a cretaceous or fibroid state, *i. e.*, of tubercle cured.

Flick[2] says "were it not for autoinfection most cases of tuberculosis (outside of the cranium) would get well. In every case which has ever come under my observation, there was a decided effort on the part of Nature to establish a cure."

Loomis[3] presented to the American Climatological Association an analysis of 41 cases dead from non-tuberculous disease, in which there were traces of cured tuberculosis. In 38 patients the lung showed a firm adhesion to the costal pleura. (Section showed numbers of fibrous nodules scattered throughout the apices, continuous with adherent pleura.) Cheesy or calcareous masses were usually found in the center of these fibrous nodules. Six cases showed small closed cavities. In a few instances linear cicatrices were observed as marking the site of closed cavities. In two instances the entire upper lobe of the lung formed a homogeneous fibrous mass. Histological examination showed a more or less completely organized fibrous tissue. This tissue had originated either by a small-celled infiltration of the interlobular tissue of the alveolar walls or of the tissue about the vessels or bronchi; by contraction, the occlusion of these was produced. Tubercle bacilli were found in one or two sections. The result of inoculation experiments varied.

Coats[4] reports that in 131 autopsies performed within ten months, 28 showed active tuberculosis; of the remaining 103, 24 cases, or 23 per cent., showed evidence of healed tuberculosis.

Fowler,[5] in an analysis of 1943 autopsies at the Middlesex Hospital, between 1879 and 1886, found that 177, or 9 per cent., showed obsolete tubercle in the lung. Subsequent to this, out of 445 consecutive autopsies, 42, or 9.4 per cent. are reported by Martin[6] as showing retrograde tubercle.

Wolff[7] reports after an interval of fifteen years that of patients suffering from marked tuberculosis who were discharged from Brehmer's famous institute at Goerbersdorf 8 per cent. can be considered cured.

H. P. Loomis,[8] analyzing 1146 autopsies at Bellevue, reports as follows: (1) Out of 763 dying of non-tuberculous diseases 71, or over 9 per cent., at some time in their lives had had phthisis from which they had recovered. (2) The new fibrous tissue by which the advance of the disease was apparently checked and the cure effected developed principally by round-cell infiltration of the interlobular connective tissue which in some instances had increased to an enormous extent. Some of the new fibrous tissue was formed later by round-cell infiltration in the alveolar walls and around the blood-vessels and bronchi. Pleuritic fibrosis appears to be secondary to tubercular processes in the lung substance. The interlobular connective tissue is the primary and principal source of the fibrosis. (3) Tubercle bacilli were present in the healed areas in three out of twelve lungs examined. These healed areas did not differ in gross or microscopical appearance from those in which they were not found. (4) Thirty-six per cent. of all cases in which the lungs were free from disease showed localized or general adhesions of the surface of the pleura.

Knopf, in a recent address at the annual meeting of the Conference of State and Provincial Boards of Health of North America at Detroit, says: "The greatest chance of a predisposed individual being taken sick is between the age of puberty and thirty. The chances of the disease becoming healed without ever having been discovered are between 20 and 25 per cent. I am in position to verify this percentage by statistics which I have compiled for my book on tuberculosis. Besides reviewing the vast literature on the subject I addressed three hundred letters of inquiry to the leading pathologists of the world, and, as a result, I can say that out of every 100 autopsies made on people having died accidentally or of disease other than tuberculosis, 20 to 25 showed evidence of healed tuberculous lesions (cicatrization or calcareous formation). The chances for the disease being cured in from six to nine months, if it is discovered at an early period, are at least 50 per cent."

Such, then, are some of the pathologic and

[1] Read before the Vermont State Medical Society.

clinical proofs of the curability of pulmonary tuberculosis. They are by no means exhaustive of the subject, but sufficient, I believe, to establish the fact that from 10 to 50 per cent. of cases, depending upon the individual resistance to the disease, and the timeliness with which treatment is begun, are curable.

Treatment.—Within a generation, or even less, the opinions held in regard to the treatment of phthisis have undergone important changes. Following Koch's discovery of the tubercle bacillus, the therapeutist hoped to cure the disease by killing the germ in the respiratory organs and passages. To accomplish this end the introduction of various germicides into the air-passages and the lung was tried. Intrapulmonary injections and inhalations of vaporized solutions of different germicides occupied the professional mind for a time, until they were proven by bacteriological experiment and clinical experience to be utterly useless.

Tuberculin is accredited as yet, by the majority of observers, with no field of usefulness except in that of diagnosis of animal tuberculosis. Many laboratory workers still cling to the hope of destroying the bacillus, or its pabulum, by a modified tuberculin, or by some antitoxin not yet discovered.

At the recent Congress for Hygiene and Dermatology, held April 12th, 1898, in Madrid, Professor Behring, the discoverer of diphtheria antitoxin, said that it has been so far impossible to obtain from mammals a remedial antitoxin which acted with certainty in man or animals, and he would have to look somewhat skeptically upon the antitoxin treatment of tuberculosis, had not Ransom in his (Behring's) laboratory in Marburg discovered a species of birds which met the requirements for the production of an effective tuberculosis antitoxin more satisfactory than do mammals. What might be gained in practice by this surprising as well as encouraging fact must be left, he said, to future developments. After referring to some of the conditions that obstruct a rapid progress in combating human tuberculosis with a specific antitoxin, Behring arrived at the conclusion that "it will still take a long time before we shall be able to speak of a practically serviceable serum-therapy of tuberculosis." Hence, as we cannot kill the tubercle bacillus directly by a germicide, or successfully combat its baneful influence by an antitoxin, we are compelled to attack him indirectly, endeavoring to render the tissues of the host, our patient, an uncongenial soil to live upon. And this we accomplish by improving the condition of our patient by the aid of food and hygienic living in the open air.

Dujardin-Beaumetz,[9] speaking of the therapeutics of phthisis, says, "We must fall back upon alimentation and hygiene; and after alimentation in importance comes climate. Oxygenation is the great point and as much open air as possible, no matter where it is, but best where the temperature is not over 60° F. in the winter. In a word, we have to confess that we are reduced to alimentation and respiration of pure air in this disease." The late Dr. Loomis said that six meals should be taken in the twenty-four hours; that the food taken at any one meal should be such as is digested in the stomach or intestines alone, *i. e.*, fats, starches and sugars should not be mixed with albuminoids, to any extent, and that no food should be taken while suffering from fatigue, worry or excitement. Rest is the great conserver of energy, and as frequent and prolonged periods should be taken as the patient's condition demands. Exercise for the most part should be passive, never violent, nor carried to the point of fatigue. Anything which markedly quickens the pulse is a distinct injury to a phthisical patient.

The neglect of these simple rules of hygiene and diet many a time has cost a sufferer his life, even when he was living under the most favorable climatic conditions, while their strict observance under medical supervision has oftimes resulted in a cure. Although an atmosphere free from moisture, with abundance of sunshine and an altitude of from two thousand to five thousand feet above the sea, is the ideal one for a consumptive, the results which of late have been obtained in sanatoria, whatever their geographical location, are so distinctly favorable as to prove conclusively the paramount importance of open-air treatment, strict hygiene, and over alimentation, or forced feeding.

The belief is gaining ground among modern phthisiotherapeutists that no climate is a specific for phthisis, and that more permanent results may be obtained by curing these cases in the early stage of their disease, near their homes where they are afterwards to live and work.

The least favorable results obtained in sanatoria devoted exclusively to the treatment of consumption are, according to Knopf (*Medical Record*, February 13, 1897) as follows: Absolute cures, 14 per cent.; relative cures, 14 per cent.; amelioration, 42 per cent.

The Chicago Presbyterian Hospital.—The work of raising funds for the purpose of enlarging and improving this hospital has just begun, and a circular has been issued requesting subscriptions. The objects for which funds are desired are a new electric-light plant, $6,000; for the ladies' furnishing fund, $3,000; for 16 additional beds, $1,000; for a steam sterilizer, $1,000, and to meet the deficit, $3,500.

CLINICAL MEMORANDUM.

LATERAL SINUS THROMBOSIS AND ACUTE SEPTOMENINGITIS BOTH COMPLICATING ACUTE SUPPURATIVE OTITIS MEDIA; COMPLETE PERFORATION OF THE CRANIAL WALL ABOVE AND EXTERNAL TO THE ANTRUM.[1]

By WENDELL C. PHILLIPS, M.D.,
OF NEW YORK;
SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL; ADJUNCT PROFESSOR OF OTOLOGY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

Case I.—M. F., aged fifty years, presented himself at my clinic at the Manhattan Eye and Ear Hospital, November 12, 1898. Eight weeks previously he had suffered from a severe pain in the left ear, followed in a few hours by a very slight discharge. The discharge lasted at intervals up to three weeks previously, since which time there had been none. During this time the pain had been almost constant. About two weeks before admission leeches had been applied over the mastoid by his family physician. This pain although localized generally over the region of the mastoid gradually extended over the left hemisphere and especially over the lateral and longitudinal sinuses. For the past two weeks he has suffered from chills and vomiting. The chills have increased in frequency and have been accompanied with considerable prostration. During the time of the first examination he had several distinct rigors. His appearance was somewhat septic and his tongue coated. The membrani tympani looked very thick and fibrous and with slight bulging over the attic region. There was no swelling over the region of the mastoid and but little tenderness.

The patient is poorly nourished. The skin dry and appeared to have a somewhat icteroid hue. Tongue thickly coated with a grayish-brown furring. Bowels constipated. Pulse 110, but weak and somewhat irregular. Temperature 101.4° F. Patient complains of pain over the left side of the head, especially over the mastoid, which is increased slightly on pressure over that region. No swelling nor edema over the mastoid. There is a very slight mucopurulent discharge from the canal. The patient's general appearance, history, and his symptoms led me at the very first examination to feel that this was a case of infective sinus disease, and this diagnosis was ventured. His symptoms seemed to me clearly to warrant such a diagnosis, and they certainly followed out the symptoms of this disease as decribed by MacEwen.

The patient consented to operation which was immediately done. He even had a chill just before the administration of the anesthetic. Previous to opening the mastoid wound a paracentesis was done, but no pus was found. The usual mastoid opening was made. The surface of the bone was somewhat congested and blood oozed freely from the surface generally. With gouge and chisel the mastoid table was removed, the cells opened and the antrum exposed, and through-and-through drainage was established, but with no sign of pus. Attention was then directed toward the mastoid tip, but not until the end cells had been reached was there any pus found, and then but a very small quantity.

The bone in this case was unusually flinty, so much so that several chisels were broken. The lateral sinus was then exposed and, not pulsating, it was opened for about one and a half inches, no bleeding followed the incision. There was no indication of any involvement of the internal jugular vein.

The incision extended from above and posterior to the angle through the sigmoid and well down toward the jugular bulb. Small masses of clotted blood were then removed from the sinuses with a curette. The curette was passed downward and all masses removed until there was slight bleeding. Posteriorly a curved groove was passed far backward and all granulation masses and clots were removed. Slight bleeding was established from the region of the torcular and the wound was thoroughly cleansed and both sinus and wound packed with iodoform gauze. The patient suffered considerable shock, but reacted promptly under hot applications and stimulants.

On November 13th the general condition seemed considerably improved. The wound was dressed and found perfectly clean and dry and the sinus wound was closed. After the operation his temperature became normal and at 3 A.M. the following morning it had gone down to 97° F. By noon of the same day it had reached 102° F. For several days the temperature varied from 100 to 102° F. and did not again reach normal until November 21st and even after this time it varied until November 22d, when it became normal and from that time remained practically so until his discharge.

November 15th, the wound was dressed and found clean and dry. November 17th, the wound was dressed and there was a slight serosanguineous discharge near the jugular bulb. This was cleaned with peroxide of hydrogen and dressed as usual. November 21st, the wound dressed dry and clean. The patient complained of pain in the limbs. He was given milk-punches and one-sixtieth of a grain of strychnine three times a day. November 25th, the wound dressed, a small area of exposed bone was found in the sinus. December 6th, wound was dressed, the opening in the antrum closing up, dressing was clean and dry. December 26th, condition the same. Area of exposed bone nearly covered.

From January 1st the sinuses were treated by the carbolic-acid method, as described in a previous paper, where it will be seen the wound closed in fourteen days. The case has since remained well and the man has returned to his usual occupation.

The chief point of interest in this case is the

[1] Read before the American Laryngological, Rhinological and Otological Society at its fifth annual meeting.

fact that the diagnosis of infective sinus disease was made in a comparatively early stage of the disease and with but slight mastoid or middle-ear symptoms, thus doing away with the necessity for the more radical operation of the opening or removal of the internal jugular vein.

The advantages of an early diagnosis in sinus disease cannot be overestimated and it would seem to the writer that our efforts should be largely expended along this direction. To be sure many of these cases do not come under our observation until they have become extreme, but in the light of present developments along this line even the general practitioner will gradually come to recognize the importance of the help of the otologist even in the care of simple suppuration.

Case II.—M. B., aged forty-seven years; housewife; was first seen October 29, 1898. Her history is as follows: Three weeks ago she began to have pain in the right ear. For many years she had been subject to neuralgic pains in the head, which were usually worse on the left side. The ear began to discharge, after a few hours, a creamy pus, which continued. The discharge was rather profuse, with pain more or less severe over the right side of the head. Three days before admission to the hospital the pain became very severe and seemed to localize behind the ear. She never had had previous attacks of suppurative middle-ear disease. Up to the time of her admission to the hospital she had attended to her usual household duties, and while suffering considerable pain she had been up and about all the time. She had not had any chill, fever nor vertigo. The diagnosis of acute mastoiditis was made and she was admitted to the ward.

The patient was a well-nourished, strong looking woman. Her complexion was slightly pasty and her mucous membranes anemic. Deep pressure over the mastoid elicited pain and there seemed to be very slight swelling over its upper portion. Calomel was administered internally, and, believing it to be a case of really acute inflammation of the mastoid, the ice-coil was used. The canal was cleansed with a hot boric acid douche every two hours.

October 30th the swelling had subsided and there was no pain on pressure over the mastoid, but the patient complained of headache, mostly occipital. In the afternoon she had a very slight chill which was followed by sweating. Her temperature at the time of admission had been 103° F., but it subsided and by 3 A.M. the following morning had reached nearly normal. October 31st she still complained of the occipital headache, but pain over the mastoid was absent, swelling and the discharge were somewhat lessened. The ice-coil was discontinued. The existing pain was more general in character and the patient complained very little of the ear. November 1st, patient slept well last night. Still complained of headache all over the head. November 2d, less headache, but now complains slightly of pain in the lumbar region and extremities. No increase of pain on pressure over the painful area and no signs of inflammation of the joints. November 3d, patient did not sleep well. Still complains of pain in the back and limbs. November 3d, did not complain of any increased pain in the head and there was no increase of tenderness of the mastoid tip, although it remained slightly tender.

Patient was up and about the ward. The temperature had remained normal. During these days the pulse had varied from 80 to 102 and the temperature had at no time been above 102° F., remaining most of the time at from 99 to 100° F. On this day I was detained and did not get to the hospital, so I did not have an opportunity to examine her. November 4th, during the night the patient became somewhat restless and about 4.30 A.M. the night nurse first noticed a change for the worse, but even at this time the patient

was out of bed and used the commode, but her mental condition was not good and in a short time she became somewhat delirious, and still complained of pain in the back. The condition became rapidly worse and at 6.45 A.M. she was unconscious, pupils contracted, reaction sluggish, particularly in the right eye, limbs became somewhat rigid and semiflexed, the face pallid and the skin cold. I was telephoned for and reached the hospital at 7.45 A.M. At this time there was no pupillary reaction, the respirations were shallow and there was loss of sensation in the left arm. The face had now become flushed and she was perspiring freely. At this time it was almost impossible to count the pulse, but it had gradually become slow. At 4 A. M. it was 60. Directions were given to prepare for operation, but her condition became so rapidly worse that it was abandoned and she died at 10.30 A.M.

Autopsy was performed the same day. The tympanum and mastoid were full of pus, the dura over a portion of the right side was thickened and adherent to the petrous portion, otherwise the dura was in a healthy condition. There was a subarachnoid infiltration of pus, indicative of general leptomeningitis. All the sinuses were in a

perfectly healthy condition. Careful section of the brain-tissue showed no abscess cavities in either cerebrum or cerebelli. The entire mastoid process, excepting the tip, was one large abscess-cavity. There was a perforation through the external wall nearly one-fourth of an inch in diameter. The internal wall was entirely gone and the necrosis had extended entirely around the sinus and pus had perforated the adherent dura posterior to the tegmen tympani. The walls of the sinus were somewhat thickened. From the appearance of the specimen the pus seems also to have entered the labyrinth. The brain-tissue was not involved, there being no abscess of cerebrum or cerebellum. (See Fig 1.)

This patient was examined by several members of the staff during the early part of the time she was in the hospital, but no one suggested a cerebral complication. The conclusions to be drawn from this history would seem to be: The ice-coil should not have been used; that it masked the symptoms and reduced the external inflammatory swelling, the tenderness and temperature, there can be no doubt. An early operation would have saved her life. Further, that the extensive leptomeningitis could possibly have been present in a case manifesting so few meningeal symptoms either of the eye, or of the mental faculties, or of loss of sensation and motion, seems almost incredible. It would almost seem that there must have been a sudden escape of pus through the perforation and that its presence over so large a surface of brain-tissue gave rise to the sudden condition of shock from which she suffered early on the morning of her death. In all cases of mastoid inflammation in which there is no external swelling or even marked indications of the disease, the ice-coil should be resorted to with caution.

Autopsy showed tympanum and mastoid full of pus with a perforation in the roof of the tympanum. No sinus involvement. Subarachnoid infiltration of pus. No abscess of cerebrum nor cerebellum. Microscopical sections taken from cortex on left side of frontal lobe show thickening of arachnoid; a subarachnoid infiltration of densely packed leucocytes, many of which are polynuclear; slight thickening of the blood-vessels which are full of red blood-cells. The pia mater is apparently thickened, but is almost indistinguishable from the infiltration. The leucocytes follow slightly the processes of the pia, which dip into the cerebral tissue. The indications are, therefore, that the cerebrum would soon have become involved. The right optic nerve shows swelling of the nerve-bundles which encroach on the connective-tissue interspaces. The sheath is slightly distended. The left optic nerve is normal. Diagnosis: Leptomeningitis. Signed: C. W. Kinney, M.D., and E. S. Thomson, M.D.

Drs. Weir and Bull Resign.—Upon notification of their recent appointments at Roosevelt Hospital, both these gentlemen resigned their positions at the New York Hospital.

MEDICAL PROGRESS.

Ankylostomyasis in Puerto Rico.—Cases of severe anemia have been very frequent in Puerto Rico for many years and are usually attributed to poor food, malaria, or the peculiarities of the climate. B. K. Ashford (*N. Y. Med. Jour.*, April 14, 1900) has recently investigated twenty rather typical cases with the hope of discovering some specific cause, and from nineteen of these patients he has obtained the eggs of Ankylostoma duodenale. The conditions are most favorable for the spread of this condition since the island is very thickly populated, the food poor and carelessly prepared and sanitary precautions are almost unknown among the poorer classes. The symptoms are variable, but usually consist of poor appetite, some nausea and vomiting, pain in the epigastrium, either constipation or diarrhea, swelling of feet and ankles, dizziness, headache, progressive debility, fever sometimes but no chills. There is seldom much loss of weight. The anemia is frequently severe and accompanied by the usual secondary signs. A careful blood-examination was made in all the cases and it was found that a low hemoglobin average and very low color index were the rule. Leucocytosis when present was probably due to complications. Normoblasts were frequently present and sometimes megaloblasts. Poikolocytes were common although some authorities deny this. A marked eosinophilia was noticed in many cases, even forty per cent. in one patient. A thorough investigation has not yet been made, and the number of patients examined thus far is so small that it is impossible to draw any conclusions in regard to the prevalence of the disease in that island, but it seems reasonable to suppose that a goodly percentage of the poorer people are thus afflicted. Thymol and aspidium were successfully used as anthelmintics.

New Method of Printing Books.—The *New York Medical Journal* (April 14, 1900) contains an article by F. G. Murphy endeavoring to show how injurious books are to the eyes. He shows how the curved page of a book when opened causes a constant change of the focus of the eye as it reads from one side to another, necessitating a continued effort on the part of the ciliary muscles. The light also usually falls unequally upon both sides, further interfering with a continued clear field of vision. He suggests, therefore, that the printed lines run parallel to the binding instead of at right angles to it so that all parts of the line would be at equal distance from the eyes and be equally lighted.

Pseudoneuralgic Form of Chronic Vertebral Rheumatism.—H. Forestier of Aix-les-Bains, who has had a wide experience in the treatment of rheumatism by the general douche-massage method, reports several peculiar cases in the *Medical Record* (April 14, 1900). The patients are slightly bent forward and cannot straighten the

body without great pain. They walk slowly, feet far apart in many instances. The neck is not involved and the patient is not so stiff as in the Bechterew type. They complain of various pains irridating from the back, intercostal pains, girdle pains, radiating through the lower limbs simulating sciatica. They are increased by movements of the trunk and a very peculiar feature is the backache in the early morning or when the patient has been lying down for some hours. No marked sensory troubles, no paresthesia, or no trophic changes exist, but there may be a certain degree of wasting and flaccidity. The knee-jerks are usually exaggerated. An examination shows no deformity of the spine, but an absence of the normal lumbar curve or a slight posterior curve. There is no ankylosis, movement being possible, although causing great pain. The stiffness is due to the protective contraction of the muscles. Tenderness on pressure is marked along the spines and lateral processes, and also along the lower intercostal spaces and over the upper sciatic nerve. The dorsolumbar region is thus mostly affected, the neck being rather seldom involved. There is no tenderness in the loins which is not in favor of a primary myosotis. Most patients give a history of more or less trouble with acute or subacute articular rheumatism. The treatment employed at Aix-les-Bains is to give the patient a general douche-massage applied by two masseurs, especially to the back, the patient lying in a reclined posture. The temperature of the water is about 85° to 90° F., and the massage is continued for ten to twelve minutes.

Myocarditis Following Rheumatism.—Endocarditis and pericarditis are, of course, always carefully watched for during and after an attack of acute rheumatism and that they account, in a of the signs pointing to those conditions is usually considered sufficient evidence that the heart has escaped the rheumatic poison. In the *Bristol Medico-Chirurgical Journal* (March, 1900) T. Fisher expresses the opinion that myocardial changes are not at all infrequent complications of acute rheumatism and that they account, in a great measure, for the variability in the severity of symptoms accompanying valvular lesions. He reports several acute cases of rheumatism resulting fatally in which no pericardial or endocardial signs were noted and in which the autopsies disclosed an advanced myocardial degeneration with very little endocardial change. The weakening of the cardiac muscle may result in a dilatation and a relative insufficiency of the mitral valves, which may stimulate an active endocardial murmur.

Early Diagnosis of Aortic Aneurism.—An early diagnosis of aneurism is of considerable importance, not only on account of the more accurate prognosis of the case which may be given, but also because the treatment is of far greater value if begun in the early stages. M. Schmidt, a laryngologist, has reviewed the symptoms of this malady in the *Medical Chronicle* (March, 1900), laying special stress upon the two methods of diagnosis which have been made use of during the past few years, tracheal tugging and the Röntgen rays. Of his 54 cases, 38 had paralysis of the left vocal cord, and in 5 there was paralysis of the right vocal cord. Out of 31 cases in which tracheal tugging was tried it was demonstrated in 19, and he regards it as one of the most decisive symptoms in the early stages. The illumination by means of the Röntgen rays is most satisfactory, provided the tumor is large enough to be visible by the side of the vertebral column. A number of radiographs are shown in which the diagnosis could hardly be mistaken. Among other diagnostic signs he mentions dulness over the manubrium sterni and, close by it, diffuse pulsation in the upper intercostal spaces, and the differences in pupils and radial pulses. The aneurismal murmur is very inconsistent, Sarcoma of the mediastinum may simulate aneurism, since it may present marked pulsation. If, however, one meets with a recent paralysis of the left vocal cord in a man of middle age; if tracheal tugging and inequality of the pulse are present, as well as pulsatory signs in the region of manubrium; if the Röntgen rays show the shadow of a pulsating mass, one is certainly justified in making the diagnosis of aortic aneurism, since it is by far the most frequent tumor of the mediastinum. Although syphilis is, no doubt, the chief predisposing cause, the author lays considerable stress upon trauma and strain. Only two of his cases were females, and he quotes many statistics to show that heavy work is an important factor. As regards treatment potassium iodide is always used and, when a history of syphilis is obtained, mercurial inunctions are indicated, at least for a time. He also advises absolute rest in bed and a marked reduction in the fluids. Trefnell's reduction of fluids to 240 grams in twenty-four hours can be reached only gradually, and this diminution must be kept up for several weeks, although it is not always possible to limit the fluids to such a small amount. The internal use of calcium chlorate to aid coagulation of the blood has not proven efficacious. In the hands of some electrolysis seems markedly beneficial, but it is a very dangerous procedure.

Actinomycosis.—This occurs usually in the cervicofacial and pulmonary regions, but has also been found, says Antonin Poncet (*Bull. de l'Acad. de Méd.*, April 2, 1900) in the intestine, liver, kidney, breast, and in the regions of the umbilicus, bladder, prostate, anus, vulva, meninges, and brain. The diagnosis is made clinically by the subacute or chronic course with occasional exacerbations, the hybrid aspect, both inflammatory and neoplastic, the pleurality of the fistulæ and their torpid, capricious evolution with cicatrization of old fistulæ in the immediate neighborhood of fresh foci. About the face and neck it is often quite painful, and there may be early tissues from involvement of the muscles, yet, in

spite of numerous fistulæ and ulcers, there is no glandular enlargement. The diagnosis is confirmed by finding the characteristic yellow granules with a rayed appearance under the microscope, yet these may be discovered only after repeated examinations, and sometimes not until months after the clinical diagnosis has been positive. These yellow grains are abundant only in recent foci and the rayed appearance may be replaced by other forms of the parasite, the incurved mycelium, the branching, and the spore forms. In old fistulæ the fungus is deeply embedded in the walls of the tract; in mixed infections it often cannot be found at all. The disease is most common among those who handle grain, and the primary focus is almost always in the alimentary tract. The intestinal and liver lesions are sometimes taken for neoplasms. The prognosis is unfavorable, especially if neighboring soft tissues have been infiltrated; the temporomaxillary type with involvement of the muscles is incurable, and invasion of the base of the brain may result in early death. All the lesions are very persistent, recurrences are common, and metastases have been frequently met with. Where possible, free excision promises the best results, and in all cases, even if operated upon, the iodides should be given in large doses, up to three drams a day. This is not a specific, but in many instances retards the growth of the fungus. In pulmonary cases, inhalation of eucalyptol has proven of benefit.

Tuberculins and Their Use.—Two different preparations have been used under the name of "tuberculin" for the treatment of tuberculosis. They have been distinguished by the names "old tuberculin" and "T. R." After describing the method of preparation of each of these tuberculins and citing the opinions of certain authorities on their use and the results obtained, E. A. De Schweinitz (*Jour. Am. Med. Assoc.*, April 14, 1900) arrives at the following conclusions: The "old tuberculin" apparently has a decided curative action on lupus. It is a valuable diagnostic agent, both in animals and man, and it should be used very much more extensively than heretofore, in diagnosing incipient cases. From numerous experiments on man and animals, here cited, it appears that in general "T. R." has given no better results than those which were secured by the use of the "old tuberculin," except, perhaps, that the secondary symptoms have not been so pronounced. A lack of uniformity in the character of the "T. R." may account for these differences. The serum treatment of tuberculosis must be regarded as still in the experimental stage, but deserves further study. The writer holds the opinion that the results obtained with the "old tuberculin" and "T. R.," and a careful study of the poisons of the tuberculosis germ, indicate that in incipient stages, the disease may perhaps be arrested and immunity secured by injecting the products of the bacilli freed from the necrotic principle, or by treating the patient with a serum which will neutralize the necrotic poison and a subsequent use of the products of the bacilli free from the necrotizing agent. A solution of these poisons free from the necrotic principle may be obtained from attenuated cultures.

Treatment of the Navel.—The chief principles to be observed in the treatment of the navel following birth are, according to F. Ahlfeld (*Centralbl. f. Gyn.*, No. 13, p. 337), shortening of the cord to the recognized minimum, touching up the stump and vicinity of the navel with 95 per cent. alcohol, then placing a layer of sterilized cotton which is to remain on for five or six days, only being removed in case of its becoming moist with urine. Especially may it be noted that after the birth of the child the cord is to be cut about 3 to 4 inches from the navel, after carefully tying it off with linen tape. Then, after the bath, the secondary shortening is to be performed. This consists in tying off the cord about $^2/_5$ inch from the navel and a little beyond this the cut is made. Now the aforementioned moistening with alcohol is to be done and the sterile cotton wrapped over it. The author never uses silk ligatures for tying off the cord, as it frequently happens that a hematoma of the cord follows a too tightly applied silk thread. The suggestion that a cautery-scissors be used to cut off the cord about one-half inch from the child's abdomen, Ahlfeld scores as being too dangerous in its application.

Antipneumococcus Serum.—Alexander Lambert (*Jour. Am. Med. Assoc.*, April 14, 1900) discusses the action of the various pneumococcus sera, as obtained from man, horse, dog, rabbit, and turkeys, and cites the results obtained by a number of investigators. He has used serum, prepared by himself from horses, in twelve cases of pneumonia, with nine recoveries and three deaths. The impressions received from these cases were: (1) The serum seemed to cause a slight reduction of temperature and an improvement in the pulse. (2) It did not cause a crisis in any case, nor did it seem to cut short the pneumonic processes. (3) It did cause the disappearance of the pneumococci from the general circulation in one case, although it did not prevent the development of an empyema, and the patient recovered. (4) The serum seemed to be of decided benefit in one patient with double lower pneumonia complicated with a furious delirium tremens, who had a relapse with a double upper and right middle-lobe pneumonia, but finally recovered. (5) The serum had absolutely no effects in two alcoholic patients who died. (6) The serum did not affect the leucocytosis, except in one case in which it was increased by 10,000, an hour after the injection, but this had fallen again the next day. While the writer believes the serum did marked good in two cases, in others it was useless. He has not continued to use the serum because it did not seem to shorten the duration of the disease, or to hold in check the pneumonic processes within the

lungs, or to bring about the desired "crisis." In certain cases the pneumonia serum seems to prevent a general pneumococcus septicemia and in these it may prove valuable, but until a serum is obtained which will cut short the disease processes, Lambert thinks the usefulness of the anti-pneumococcus serum will be limited.

Pyogenic Origin of Chorea Rheumatica.—Those cases of chorea, which have been thoroughly studied from a bacteriological point of view, give evidence that the rheumatic cases are undoubtedly due, in the great majority of instances, to pyogenic micro-organisms. This is the result which S. Mircoli of Genoa (*Berlin. klin. Woch.*, April 2, 1900) has established through his investigations. In 17 cases of rheumatic chorea, there were found 14 of undoubted bacterial infection, with the staphylococcus as the prevailing germ and 3 with the diplococcus lanceolatus as the etiological factor. In two of the cases, the staphylococci were demonstrated in the blood of the patient. It has been said that the staphylococci and streptococci cannot exist in the body without giving rise to pus formation. It is, however, not to be forgotten that varying degrees of virulence are possessed by different germs and that this depends greatly on the soil in which the germs are imbedded. Furthermore, the difference between suppuration and phlogosis is one of degree only. Therefore, in those cases of germ origin there need not necessarily be any pus formed—the inflammatory processes stopping at the congestive stage. It is, besides all this, incorrect to suppose that acute rheumatism never goes on to suppuration. Extensive experiments made by the author on rabbits proved to his satisfaction that in the rheumatism brought on artificially in these animals, there were organic and functional changes simultaneously in the heart, kidneys, and blood. This may explain the varying symptomatology often encountered in the cases under discussion. Mircoli claims priority in the matter of the demonstration of the pyogenic origin of chorea rheumatica and its bacteriological connection with the ordinary rheumatic processes.

Cure of Cancer.—Cancroin has frequently been used in the non-surgical treatment of cancer, but, owing to the fact that this substance can be given only in small doses, the process of cure is at best only a slow one and the sufferers often lose patience, so that but little opportunity is afforded to test the true value of this method. A. Adamkiewicz (*Klin. therap. Woch.*, March 25, 1900), however, reports a well-advanced case of cancerous peritonitis in which the true worth of cancroin was settled beyond doubt. The main symptoms from which the patient was suffering were an enormous ascites and a rapidly advancing cachexia which demanded immediate aspiration. The examination of the fluid and the presence in the peritoneal cavity of numerous hard nodules made the diagnosis of cancer positive. Cancroin injections were then resorted to with the gratifying result that the dropsy did not recur and that the tumors steadily diminished in size. Two years later the patient was again seen by the author and appeared to be in perfect health.

Naftalan.—P. G. Unna (*Monatshft. f. prak. Dermatolog.*, April, 1900) has taken pains to ascertain the realm of usefulness of naftalan in skin diseases. He finds that in all deep-seated, chronic lesions it is distinctly without benefit, but that wherever over-irritation is present and a sedative would be in place, its use is indicated. Among this class certain forms of eczema and dermatitis, but especially universal eczema and psoriasis with exfoliation and a tendency toward malignancy, are included, the good results showing themselves in a lessening of the hyperemia and pruritus. Naftalan consists of a substance similar to vaseline with some pigment and soap. The latter gives a good consistency, easy miscibility with water, and ready absorption.

Death from Psychic Insult.—Under the name of delirium nervosum Dupuytren and, more recently, of operation-psychosis, the results of psychic insults have for some time been known to surgeons. F. Pagenstecher (*Phila. Med. Jour.*, April 14, 1900) reports a case, which he believes to be the first of its kind reported, in which death was the outcome of a psychic insult. A detailed history of the case is given, of which the following are the main points. The patient was a merchant, 51 years old, who had never been ill or injured in any way. He was not a drinking man. One day while at his desk sharpening a pencil he cut his thumb and his pen fell from his ear upon the wound staining it with ink. His nephew tried to wash off the ink and the man went to a physician. He was very much excited and told the doctor that he was very much worried for fear of blood-poisoning, as his ink was so poisonous. He complained of pain in his left arm and was anxious to notify his accident insurance company. The physician found, on the ball of the left thumb, four small vertical scratches, although all extended only to the true skin and could scarcely have bled. These scratches were each about 1 cm. long and one of them was stained with ink. The patient wanted the doctor to amputate his arm if he thought it necessary. A dressing was put on the thumb and the man went back to his factory. Later in the day he went home and complained of the pain in the arm. Then he went to see his family physician, who scraped away the ink with a knife, used bichloride on the thumb and put on a fresh dressing. The patient felt the poison working its way up to the axilla, and told this physician also to amputate the arm if it was necessary. After this dressing was put on the patient fell in a fainting fit with profuse perspiration, and because of this and because he thought he felt enlarged axillary glands this physician thought that there were symptoms of blood-poi-

soning, but not enough to justify amputation. The patient passed a bad night and was very much excited when his physician called the next morning with an associate. He demanded amputation of his arm, was delirious, had auditory hallucinations, made arrangements for his own funeral, complained of headache, and tossed restlessly about the bed. At this time his pulse was 70, soft and regular, his temperature was not taken. After the doctors left, a nurse being with him, his face and mouth twitched and he crouched in a corner. When quieted he began to tell the nurse all his private affairs. Then the twitching of his face and his nervousness began anew. The patient's face was yellowish-white and the pulse was regular. At 4 P.M. the writer was called to operate and found the patient free from delirium, but most positive that he was going to die, and that his arm must be amputated. He was fearful of the pain which would be caused by the removal of the dressing on his thumb, but said nothing when it was taken off. There was no sign of irritation in the wound, nor any appearance of infection or glandular enlargement. The statements about the painful areas on the arm were very contradictory. The patient appeared weak when he sat up, and the twitching of the face and mouth was striking. He also demanded amputation from the writer. An hour later his pulse was 72, soft and full. Two hours later the patient was in a moribund condition, the heart's beat being scarcely audible. Death was sudden and wholly unexpected. The heart continued to beat for one and one-half minutes after respiration ceased. Blood-poisoning was ruled out by the results of the necropsy, but no real cause of death was found. The writer's opinion is that the case was one of traumatic neurosis which developed into an acute psychosis. He thinks that death possibly resulted from insufficiency of the heart, and doubts that it beat after respiration ceased. Two perfect examples of Dupuytren's delirium nervosum are cited in detail as illustrating less severe results of psychic insults. The writer also discussed the predisposing causes of delirium nervosum and operation-psychoses and the cause of death in this case and cites a number of authors who have written on these subjects. This patient had a large amount of accident insurance and the insurance company presented three theories against the claim, *i. e.*: (1) That the patient committed suicide by curare poisoning; (2) that it was a case of tetanus, and (3) that it was a case of acute hysterical psychosis. The writer agrees with the last theory except in regard to the term hysterical.

Delirium Tremens.—The treatment of this condition is well outlined by C. R. Stockton (*American Therapist*, March, 1900). In the acute stages the brain is congested as well as very much irritated by the alcohol itself. To withdraw the blood from the brain, purgatives are indicated, calomel in five-grain doses, followed by a saline. The skin should also be stimulated to activity. This can be accomplished by a hot pack and hot drinks. The kidneys should also be awakened by mild saline diuretics. To allay the nervous irritability bromides and chloral are recommended, the dose depending on the size, sex and strength of the patient. For large and strong male adults thirty grains of chloral and one to two drams of bromide may be given with safety. Half this dose is to be given to a woman. The extreme depression is to be met by stimulants, such as hot beef tea, capsicum, Hoffman's anodyne, nitroglycerin, strychnine and digitalis. If great rapidity in the evacuation of the bowels is a desideratum, he recommends hypodermic injections of aloin. Half-grain doses are capable of emptying the cecum in from one to two hours. Hydrobromate of hyoscine in one-hundredth of a grain is given hypodermically. This drug is to be used with much caution. The diet of the patient must be nutritious, easily digested and palatable. Small amounts of food taken at frequent intervals are indicated.

Diffuse Septic Peritonitis.—The researches of Robinson of Chicago have demonstrated that great variations exist with reference to the absorptive power of different portions of the peritoneum. The region of the diaphragm is known, from anatomical data, to possess the greatest physiological power of absorption, since here there are large lymph trunks present and there are numerous lymph stomata which stand ready to take up and transport to the lymph system at large any toxic products which may present themselves. Next in point of anatomy available for the same purposes is the intestinal region. Here the stomata and lymph trunks are numerous, but less so than those found in the diaphragmatic areas. The pelvic areas, on the contrary, present a condition which is in marked contrast to these former. Here the small lymph capillaries are numerous, but the stomata and lymph trunks are comparatively few. From such anatomical facts it may readily be inferred that toxic products, when found in the pelvic region, are less liable of absorption. This clinical experience amply corroborates. Furthermore, obstructive lymphangitis is capable of occluding the smaller vessels in the pelvic peritoneum and thus limit their carrying power, whereas the larger lymph trunks of the intestinal and sub-diaphragmatic areas are less liable to be occluded by such septic peri- and paralymphangitis. It has been observed that many cases of vomiting, accompanied by some diffuse septic process of the peritoneum, have been benefited by the sitting posture and this clinical observation in conjunction with the anatomical data has led G. R. Fowler of Brooklyn (*Med. Record*, April 14, 1900) to adapt these teachings and to describe a method of treatment of diffuse septic peritonitis by drainage and by elevated head and trunk postures to facilitate drainage into the pelvis. Fowler reports the histories of nine consecutive

cases. All of these patients recovered. In all of these cases complete surgical drainage and cleansing of the peritoneal cavity was performed. The after-treatment consisted in elevating the head of the bed at least from twelve to fifteen inches. In order to prevent the sliding down of the patient, firm pillows are placed at the feet. With reference to the question of the best treatment of diffuse septic peritonitis, whether eventration or disembowelling for purposes of methodical cleaning; as well as the employment of peroxide of hydrogen solution, or the use of large quantities of decinormal saline solution for purposes of flushing out the peritoneal cavity are concerned, there may be in the author's opinion, some room for argument, but two points he commends with confidence, namely, the employment of the elevated head and trunk position, and drainage of the pelvic cavity at least by means of properly placed and protected glass drains.

Hypodermoclysis.—The chest, abdomen, thigh, axillary space, cellular tissues of the neck and back, beneath the breasts, in females, have all been advised as excellent regions for the subcutaneous injections of normal saline solution. R. C. Kemp (*Med. Record*, April 14, 1900) recommends highly the iliolumbar region, the space between the highest part of the ilium and the lower border of the ribs—in effect the loin, but rather the outer margin of the lumbar region. It is advantageous since it does not interfere with motion; it permits of the dorsal position, and the movements of abdominal and thoracic respiration are not hampered.

Diagnosis of Persistent Headache.—O. Landman (*Med. Record*, April 14, 1900) recommends the instillation of atropine in the eye for the diagnosis of certain forms of persistent headache. It is specially valuable for headaches associated with eye-strain. These pains are usually situated, when due to ocular defects, supraciliary, occipital, occipitofrontal, vertex and temporal. One type of headache he believes to be diagnostic of eye-strain. The pain is situated on the top of the head and has an area of about the size of a silver dollar; it is circumscribed and the scalp is tender. He uses a solution of one-fourth of a grain of atropine sulphate dissolved in two drams of water. Three drops of this are instilled three times a day. If the headache disappears under this mode of testing it is probably due to eye-strain and is best relieved by glasses. In old persons the test is to be applied with caution and should be discountenanced for any patients with increased ocular tension.

Flatulence and Colic in Infants.—These symptoms, which may occur unaccompanied by vomiting or diarrhea, are often due to feeding too rapidly and too much at a time; fermentation takes place in the small intestines, which become distended with gas; the infant grows restless and begins to cry. Flatulence may be relieved by one or two teaspoonfuls of equal parts of lime-water and cinnamon-water, a small dose of carbonate of ammonia and soda in peppermint-water, or a small piece of a "soda mint" dissolved in a little syrup. The amount of food should be diminished, at least temporarily, which can be satisfactorily accomplished by giving the infant sweetened barley-water or whey before nursing, and by not allowing it to nurse too often or too long at a time. In the case of bottle-fed babies the amount of food, especially of curd, should be reduced by diluting with barley- or lime-water, or, if preferred, the curd can be given predigested. Colic should be treated by large enemata (10—15 oz.) of warm water and by hot fomentations to the abdomen. The following prescriptions will also be found helpful:

1. ℞ Magnesiæ carb.....gr. iiss
   Rhei .....gr. ¼
   Syr. zingib .....mv
   Aq. menth. pip.....q. s. ad. ʒ i.
   M. Sig. Give every two hours to infant 3 or 4 months old.
2. ℞ Hydrarg. cam. cretæ.....gr. ½
   Pulv. ipec. et opii.....gr. ½
   Sacchari .....gr. ½.
   M. Ft. chart No. 1. Sig. For one dose.—*Ashby and Wright* (Northrup), "Diseases of Children."

Herpes Zoster of Mouth and Gums.—An ointment containing cocaine and morphine should be applied and a bit of cotton wool be placed between the cheek and the teeth to prevent friction. Another method consists in the application of compresses (which are renewed every two hours) wet with the following lotion:

℞ Plumbi acet.....ʒ ss
Pulv. aluminii.....ʒ ss
Aq. dest.....ʒ ii.
M. Sig. External use.

At the same time five drops of the tincture of belladonna are administered every two hours until the pharynx becomes slightly dry, and the following mixture is prescribed:

℞ Ext. gelsemii.....gr. xx
Sodii sulpho carb.....gr. xx
Aq. dest.....ʒ i.
M. Sig. One teaspoonful every two hours.

Under the above treatment the pain is said to disappear in a few hours and the course of the disease to be shortened.—*Gorgas*, "Dental Medicine."

Diuretics in Cardiac Dropsy.—

1. ℞ Potassi acet.....gr. x
   Succi scoparii.....ʒ ss
   Tinct. digitalis .....mv
   Spts. chloroformi .....mv
   Inf. senegæ (Br.).....ʒ ss.
   M. Sig. Dose to be administered three times a day to a child of from 8 to 12 years of age.
2. ℞ Potassi iodidi.....gr. ii
   Tinct. scillæ .....mv
   Tinct. strophanth .....mv
   Spts. chloroformi .....mv
   Aquæ q. s. ad.....ʒ ss.
   M. Sig. As above.—*Ashby and Wright.*

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

LICENSING MIDWIVES IN NEW YORK.

THE Plunkitt Bill entitled An Act: "Regulating and restraining the practice of midwifery in the City of New York by others than legally authorized physicians," has passed the Senate and Assembly and is now awaiting the signature of the Mayor and Governor in order to become a law. There seems to be an ideal as well as a practical side to the midwifery question. The ideal is presented in the argument that no one who possesses less knowledge than is demanded of the practitioner of medicine in this State should be permitted to practice midwifery. It is considered against public policy to lower the standard in order to provide for a class to practice midwifery even in normal labor only, as is provided in the Act known as the "Plunkitt Midwifery Bill." Imperfectly educated women must not be licensed by the State to practice midwifery and become a menace to public health, as it requires no less knowledge than that which is possessed by a licensed physician to protect the mother and child from injuries and diseases to which they are both specially liable at this time. On the other hand the argument in favor of the practical solution of the question presents the fact that midwives have always existed, and the belief that they will always continue to exist. That the work midwives do in caring for the family as well as for the mother and child makes their services invaluable to the poorer classes of the community. They deliver the mother, wash the child, cook the family meal, care for the other children, and if necessary do general housework while the mother is lying sick in bed. Midwives are often selected to do the kind of work that is beneath the dignity of a physician to do, but is essential and helpful to the family of the poor sick mother.

If midwives should be examined by a regularly constituted examining board under the control of the Regents of the University of the State of New York and a license issued to them by the State, the poor of the community would not be the prey of the criminally ignorant midwives who now practice in all the cities of this State. As there is little hope that the supporters of the ideal side will be able to abolish this class of midwives let us accept the practical solution of the question which will secure to the poor of the community better attendants by weeding out the criminally ignorant midwives who occasion so much misery, disease and death.

The objection to the present bill is that it establishes a special board of examiners appointed by the New York City Board of Health from the corps of Sanitary Inspectors. This is a fatal error and the bill should be opposed by the profession before the Mayor and if not successful there the defect in the bill should be convincingly presented to the Governor.

SPINAL CORD HEMORRHAGE.

MODERN methods of locomotion and later day necessities of haste and bustle have brought many attendant ills, not the least important of which are injuries to the spinal cord. One special type of such traumatic hemorrhages into the spinal cord has received a large share of attention and a recent and valuable addition to our knowledge is contributed by Pearce Bailey in a recent number of the *Medical Record*, April 7, 1900.

This is a condition which a few years ago was comparatively unknown and which, no doubt, often passes unrecognized at the present time. Bailey divides the conditions which may be caused by an injury to the spinal cord into three classes: First, pressure from displaced or broken-down protecting structures; second, pressure from blood poured out within the spinal canal

(hematorrhachis), and, third, primary hematomyelia.

The first class comprises the common fractures and dislocations of the spine. The symptoms are usually grave and extended and the prognosis bad. In a well-marked case there is paralysis of motion below the site of the lesion, loss of sensation and sphincter action. But the pressure on the outside of the cord may be slight and associated with it may be found hemorrhages into the gray matter, giving the symptoms also of a primary hemorrhage. It is important to bear in mind that pressure from outside affects the long afferent and efferent tracts and consequently, no matter how slight the symptoms are, they may be found everywhere below the lesion. On the other hand, primary hematomyelia may cause symptoms in the upper extremity while the lower is unaffected. The second class of cases, in which blood is poured out into the spinal canal between the cord and vertebræ, is usually associated with other lesions and is rarely, if ever, of clinical importance.

The third variety, namely, primary hematomyelia, is relatively frequent and the diagnosis important on account of the favorable prognosis which may often be given. The situation of the hemorrhage is usually in the gray matter, on account of its high vascularity and the lack of supporting tissue. The ventral and dorsal horns are favorite sites. The white matter also may be invaded through two or more segments and even causing fair-sized cavities. The blood usually causes an actual destruction of the nervous tissue, absorption follows with the formation of new neuroglia cells. Localized hemorrhages from injury are found most frequently in the lower cervical and upper dorsal regions on account of the spinal movements. Only a few cases of disseminated extravasations throughout the whole spinal axis have been described.

When larger focal hemorrhages occur, paralysis of the upper and lower extremities usually immediately follows (the most common site of the lesion being the lower cervical region). The paralysis of the arms is due to an actual destruction of the nerve-cells and is permanent; the paralysis of the legs is due to pressure on the anterior and crossed pyramidal tracts, causing a spastic condition which gradually improves, although a flaccid state is commonly present immediately after the injury. The muscles of the upper extremities most frequently affected are the small ones of the thumb and the interossei, and thus the malady somewhat resembles progressive muscular atrophy, especially when atrophy, fibrillation and degenerative electrical reactions occur. The sensory symptoms, however, resemble those of syringomyelia, since the sensation of touch is preserved while the sensations of pain and temperature are lost; the latter being conveyed brainward along paths near the central canal.

Many of these patients almost entirely recover. When small focal hemorrhages occur the symptomatology cannot be closely defined, for the various situations of the lesions give widely different symptoms. There is not usually any loss of control of the rectum or bladder, such as is often present, at least temporarily, in large focal hemorrhages. Sensory symptoms may be absent. Anesthesia is not widespread and the crossed paralyses of the Brown-Séquard type are common. Cases of so-called diplegia brachialis traumatica, in which the symptoms consist of a flaccid paralysis of the upper extremities resulting from an injury to the neck, together with lack of anesthesia, absence of sphincter control, and no paralysis of legs, are probably due to hematomyelia.

As far as treatment of these conditions is concerned, it is important to understand that the progress is favorable and that the nutrition of the patient and especially the affected muscles should be maintained. Rest in bed, faradism or galvanism, prevention of bed sores, and the use of potassium iodide, are the usual means of treatment.

PAY AND SERVICE OF ASYLUM ATTENDANTS.

With the lessened number of hours of work in many fields, comes the renewed demand for a similar reduction in the hours of duty of asylum and State hospital attendants and nurses. The matter was thoroughly discussed before the London County Council *(British Medical Journal,* Feb. 24, 1900) by the Asylum Committee at their February meeting, and a similar movement has taken shape in form of a bill recently introduced in the New York State Legislature, for reducing the hours of duty in State hospital service to eight hours, thus making three shifts necessary for the twenty-four hours. Action is still pending upon this measure in the legislative committee.

In the great majority of asylums and State hospitals, the day attendants and nurses are on duty from six A. M to eight P. M., or from the rising to

the retiring hour of the inmates, while the night attendant or nurse is on duty for the remaining ten hours of the twenty-four. The committee of the London asylums reported against the advisability of attempting three shifts, eight hours each, because of the great expense entailed, although they deplored the necessity of a continuous duty of fourteen hours for such employees. A similar position was taken by Dr. Wise, President of the State Commission of Lunacy, who, in a recent committee hearing on the New York State bill, spoke against it on the ground of the unavoidable additional expense. The salary for this class of the service in New York State is already $1,000,000 yearly. The change would therefore necessitate $300,000 more for the care and treatment of the insane; no inconsiderable sum when we consider that the yearly appropriation for the insane is about $3,500,000 already. Taking into account that only last year the New York State Legislature cut the appropriation for salaries and wages for the State hospitals seven per cent., it does not seem that the matter will be settled for some time to come, even were it a matter of finance only.

Certainly, the confinement and responsibility of those engaged in caring for the insane in this country are too little recognized and compensated for in many States. The work in caring for the mentally afflicted is more arduous than those in charge of the physically ill in our large general hospitals, where the hours of the day- and night-work is usually equally divided. But one must bear in mind that those patients in a general hospital are mostly in bed, thus making a twelve-hour shift more practicable there than in an asylum. The compensation which the attendants in the New York State institutions receive is apparently the prevailing rate of wages when the living expenses of such employees are taken into account, although it may be said that the service pay of this State is far in advance of many others. In this connection another movement, none the less important and praiseworthy, is being agitated in New York State; that of pensioning attendants and physicians who may suffer lasting or permanent injury in the discharge of their duty while caring for the State's defective classes.

While it is justly expected that those devoting themselves to the care of the insane, both attendants and physicians, should be largely actuated by philanthropic motives, we fail to see why they should be deprived of a just compensation. Assuredly, here as well as elsewhere, it has been found in the past that the laborer is worthy of his hire.

ECHOES AND NEWS.

NEW YORK.

The Drug Clerk's Bill.—The bill regulating the working hours of pharmacists and drug-clerks in New York City has become a law.

In Dr. Fitzsimmon's Memory.—To perpetuate the memory of their son, the parents of Dr. Fitzsimmons, who died recently, have presented a pipe-organ to St. Mary's Hospital. Dr. Fitzsimmons had been connected with this institution for nearly two years.

The Governor's Signature.—Governor Roosevelt has signed the bill appropriating $1,000,000 for buildings, repairs and improvements at the State Hospitals for the Insane.

The Hospital for Crippled Children.—The State Hospital for Crippled Children, to be erected near New York City and for which $15,000 have been appropriated by the Legislature, is now being organized. Governor Roosevelt has appointed Dr. Newton M. Shaffer to be Surgeon-in-Chief for a term of six years. Among the managers are Bishop Potter, J. Hampden Robb, J. Adriance Bush, and George Blagden, Jr.

Mothers' and Babies' Hospital.—Through the generosity of a New York lady, this institution recently received a handsome donation for the purpose of building an amphitheater for the accommodation of students in attendance upon the clinics which are held there. Clinics in midwifery are given to students of four medical schools. This donation is strictly in the interest of medical education.

Contagious Diseases.—For the week ending April 14th, 1900: Measles, 680 cases and 22 deaths; diphtheria, 225 cases and 50 deaths; laryngeal diphtheria (croup), 23 cases and 11 deaths; scarlet fever, 158 cases and 22 deaths; smallpox, 1 case and 1 death; chicken-pox, 16 cases; tuberculosis, 237 cases and 179 deaths; typhoid fever, 15 cases and 7 deaths; cerebrospinal meningitis, 9 deaths. Totals, 1355 cases and 301 deaths.

The State Tuberculosis Hospital.—The trustees of the hospital to be established in the Adirondacks for the treatment of incipient phthisis have been appointed. They are Howard Townsend, of Manhattan; Dr. John H. Pryor, of Buffalo; Dr. Willis G. McDonald, of Albany; Walter Jennings, of Manhattan, and Frank E. Kendall, of Saranac Lake. The site is to be approved by the State Board of Health and the Forest Preserve Board. The latter will set aside 1000 acres of land for the use of the hospital, and the trustees are to purchase an equal amount.

Revision of the Pharmacopœia.—The following

resolutions have been adopted by the New York State Medical Society:

Resolved, that it is the sense of the Medical Society of the State of New York that the interests of medical science require the establishment of a Bureau of Materia Medica in order to institute disinterested investigation into the character and value of new drugs.

Resolved, that this Society recommends to the Decennial Convention of 1900 for the revision of the U. S. Pharmacopœia, the creation of such a Bureau by and under its authority, with the provision that it shall report annually upon the matters coming properly within the scope of its work. Adopted January 30, 1900. F. C. Curtis, Sec'y.

Gerry Society Remains Autocratic.—The Court of Appeals at Albany denied on April 17th the application of the State Board of Charities for re-argument of its action to compel Commodore Elbridge T. Gerry's Society for the Prevention of Cruelty to Children to submit to the Board's inspection and visitation. The Court had already decided, by a vote of 4 to 3, that Mr. Gerry's society does not come under the jurisdiction or inspection of the State Board, and the last Legislature refused to pass a bill making the Society subject to such visitation and inspection.

State Board of Charities' Election.—The State Board of Charities, at its annual meeting on April 12th, unanimously elected William Rhinelander Stewart of New York President for the eighth consecutive term, and Enoch Vine Stoddard of Rochester Vice-President for the sixth consecutive term. The other officers were continued in office, subject to the pleasure of the Board.

Operation on Dr. West.—Dr. George E. West, who was formerly Secretary of the Health Department in Brooklyn, had his left leg amputated on April 12th at the Brooklyn Hospital. The disease was tuberculosis. A brother of Dr. West had a leg amputated a few years ago for the same reason. The latter died.

Hospital Sunday Fund.—The collections of the Hospital Saturday and Sunday Association, as reported by the General Treasurer, Charles Lanier, amount to more than $74,000, nearly $4,000 more than last year. The Woman's Auxiliary collected over $9,000. The following is the apportionment of the committee made on a basis of free work performed by the various institutions benefiting:

Montefiore Home for Chronic Invalids	$5,800.00
St. Luke's Hospital	5,161.67
Roosevelt Hospital	3,530.10
Mount Sinai Hospital	4,015.59
German Hospital	3,461.64
Ruptured and Crippled Hospital	3,030.32
Nursery and Child's Hospital	2,791.45
St. Mary's Free Hospital for Children	2,057.96
Isabella Heimath	1,892.48
Home for Incurables	1,807.47
Mother's Home of the Sisters of Misericordia	1,760.04
French Hospital	1,730.52
Colored Home and Hospital	1,692.37
Sloane Maternity Hospital	1,495.41
Lebanon Hospital	1,348.81
Orthopaedic Hospital	1,313.73
Infirmary for Women and Children	1,095.39
House of the Holy Comforter	1,047.73
J. Hood Wright Memorial Hospital	964.92
Woman's Hospital	834.83
Flower Hospital	801.13
Skin and Cancer Hospital	788.59
Mothers' and Babies' Hospital	761.91
Post Graduate Hospital	757.61
St. Mark's Hospital	734.50
Beth Israel Hospital	696.01
Ophthalmic Hospital	692.46
Babies' Hospital	667.01
Eye and Ear Infirmary	666.99
New York Polyclinic Hospital	593.16
Manhattan Eye and Ear Hospital	590.08
Old Marion Street Maternity Hospital	584.36
Hahnemann Hospital	576.66
General Memorial Hospital	540.16
Ophthalmic and Aural Institute	308.95
Convalescent Home	250.00
Medical College and Hospital for Women	250.00
Total	$58,000.00

The remaining $16,000 will be turned over to institutions especially designated by the donors.

PHILADELPHIA.

Hospital Addition.—St. Mary's Hospital, Kensington, is too small for the increasing demands made upon its facilities and an addition is to be made. The new wing will be 70 by 100 feet and four stories high.

Health Report.—Deaths in the city for the week ending April 14th were 691, an increase of 12 over those of the previous week. Contagious diseases: Diphtheria, 81 cases, 15 deaths; scarlet fever, 60 cases, 8 deaths; typhoid fever, 85 cases, 15 deaths. The deaths from influenza were 46.

Phœnixville Hospital.—The new hospital at Phœnixville was dedicated April 14th, the cornerstone having been laid in 1898. The structure is four stories in height and cost $43,000. The local council of Junior American Mechanics presented the hospital with a new ambulance.

Unusual Demand for Nurses.—The demand for trained nurses is unusually large at present and at the various hospitals the supply is barely equal to the demand. This is also the case at the Directory of Nurses at the College of Physicians. Cases of Sickness are of a general nature, but influenza and pneumonia predominate.

Women's Medical College.—The semi-centennial jubilee of this college will be celebrated in connection with the commencement exercises in May. The college has made great advancement during its fifty years of existence, a new annex and a gymnasium being the most recent additions. The niece of a royal prince of India is now a student at the college. Among the graduates are a large number of medical missionaries.

County Medical Society.—At the meeting of April 11th, Dr. David Riesman exhibited a case of elephantiasis of the leg. The patient is a male, a worker in an iron mill. The swelling began four years ago, sharp pain being felt at first, and rapidly increased, nearly the present size of the leg being attained in six weeks. The chief com-

plaint now is headache and irregular pains in the abdomen, but these are attributed to the patient's occupation. No filaria have been found, although four examinations have been made and they are not believed to be the cause. The etiology is not sure, the process seeming to be one that lies between inflammation and a tumor.

Dr. Edward Martin spoke on "The Surgical Treatment of Empyemia." Prophylaxis is of great importance and consists in aspirating or draining all cases of inflammatory effusions. The opening should be made in the eighth interspace just anterior to the line of the angle of the scapula, the skin being opened with a knife before the needle or trocar is inserted. For empyema the opening is in the same interspace at the posterior axillary fold. Summary: Empyema is best prevented by promptly evacuating effusions. In a recent empyema, use the continuous siphon drainage, making an opening large enough to admit the little finger. In more obstinate cases, one inch of a rib should be resected. In long-standing cases remove the bony and muscular walls to allow closure of the cavity.

Pathological Society.—At the meeting of April 12th, Dr. S. Solis Cohen exhibited an enormous liver containing a secondary sarcomatous growth from a primary mediastinal tumor. The primary growth was in the mediastinal lymphatics or the bronchial glands. The liver weighed nearly 15 pounds. The right and left lobes were both greatly enlarged, but between them was a normal area, this leading to the diagnosis of enlarged spleen also. The latter organ was found to be normal. The clinical duration of the case was only three months. Death was caused by rupture of the liver.

Dr. H. F. Harris read a paper and gave a microscopical demonstration of "The Pathological Alterations in Bubonic Plague." The specimens upon which the study has been made were brought from Hong Kong by Dr. W. F. Arnold, U. S. N. The most important alterations are found in the lymph-nodes. In one-half of the cases the glands of the groin are first affected, 50 per cent. of the remainder occurring in the axilla. The nodes are greatly swollen, the tissues surrounding them being also swollen and often exhibiting hemorrhagic foci. In severe forms of the disease the nodes are soft, the cortical and medullary portions can rarely be distinguished, and the contents are semi-fluid or mucilaginous. The surrounding vessels are enlarged and contain pest bacilli. The contents of the node consist of granular material, cells, and cellular débris. In some instances the pest bacilli constitute more than one-half the contents of the node. The cells present consist of lymphoid and hyalin cells, many of the latter showing phagocytic forms. Some of these contain 30 or 40 pest bacilli, but the bacilli have evidently been victorious as they do not stain differently from those which are free in the node. Mast cells are also present and around some of them is a zone in which no bacilli are found, which suggests the question of their producing an antitoxin. These mast cells are considered diagnostic as they have not been found in the lymph-nodes in any other lesion. True suppuration does not occur in the glands without a secondary infection. The walls of the surrounding blood-vessels become swollen and degenerated, this accounting for the areas of hemorrhage which occur.

CHICAGO.

Appropriation by the City Council.—For the purpose of constructing an emergency hospital in the down-town district, the City Council has taken favorable action on the proposed appropriation of $2,000, as urged by the Women's Medical Club.

Drainage Canal Improves the River.—According to a report made by Professor Long, of the Department of Chemistry of the Northwestern University Medical School, the water of the Illinois River now contains fewer germs than it did before the canal was opened. Professor Long's analysis shows the proportion of impurity in the river-water this year as compared with last year. The analysis will be used as evidence against possible complaints of residents. Professor Long concludes that the increased flow of the canal will decrease further the proportion of germs.

Medicine as a Profession.—Dr. John M. Dodson, in an address recently delivered before the Sunset Club of this city, said that in this country there is about one doctor to every 600 of population, while in foreign countries the ratio is about twice as high. The average salary of a physician in a large city is approximately $2,000 a year, while in the country districts the average is about $1,500 a year. To a young man studying the proposition of entering a profession, if he has merely the question of making money in mind, there are other walks of life which offer larger inducements. The highest possible return that he knows of in the profession is about $80,000. There are two doctors in Chicago who make more than $50,000 annually, 10 who make more than $25,000, and 100 who make from $10,000 to $20,000 each year. The opportunities for original research and investigation are great. There has been a great advance in medical education, but there is much for the profession to learn, and one of the most important things is preventive medicine. He believes the time is near at hand when the physician will be paid by his client not alone for the curing of disease, but for its prevention.

Diseases of the Nose and Throat in Relation to Life Expectancy.—Dr. William E. Casselberry, in a paper read before a joint meeting of the Chicago Medical Society and of the Chicago Medical Insurance Examiners' Association, stated that diseases of the throat and nose have not as yet been accorded a prominent position as to life expectancy. The term catarrh is responsible for

the chaotic state in which nasal diseases still remain in the minds of most observers. Embodied in a question the word has its uses in eliciting information from the applicant, but the physician should ever remember that all conditions of nasal discomfort, discharge and fetor, are colloquially designated by this term catarrh, and that it is thus caused to embrace a multitude of disorders, like and unlike, trifling and grave, and from the merest functional disturbance of secretion to the widest destruction of tissue incidental to constitutional disease or malignancy. From a medical standpoint the term should be restricted to the three ordinary forms of inflammation respectively designated as simple rhinitis, hypertrophic rhinitis, and atrophic rhinitis. These, when uncomplicated, have little or no influence upon life expectancy, unless the case be one of extraordinary severity, or occurring in one of otherwise debilitated constitution. But these unimportant catarrhal affections are liable to be confounded with more serious nasal diseases which are prone to shorten the duration of life, and which the examiner, therefore, should seek to discover. Prominent among these he mentioned chronic suppuration of the antrum of Highmore, or of the frontal and ethmoid sinuses. The significance of nasal polypus with reference to life insurance rates varies with the individual case. If single or small, and with little disposition to recurrence after removal, it may add but a trifling risk, but when multiple or large, and persistently recurrent, a conservative custom would be to exact a thorough removal of the polypi as a condition preliminary to acceptance. Polypi are a frequent accompaniment and, probably, at different times, both a cause and an effect of sinus empyema, so much so that to the rhinologists their presence is instantly suggestive of a possible chronic suppuration in one or more of the accessory sinuses of the nose. In like manner asthma, while not solely caused by nasal polypi and polypoid hypertrophy in the ethmoid region, is so commonly associated therewith and aggravated thereby that it seems incumbent to take the asthmatic tendency into consideration as a possible complication which does exert a baneful influence upon life expectancy, and which, if not present at the moment in conjunction with polypus, is liable to arise in the future. In this connection he mentioned also hay-fever and hay-asthma. The former alone, he believes, is not considered a cause for rejection, but the latter, especially if severe, should be viewed with suspicion on account of its tendency to pass into common asthma, and thence ultimately into chronic bronchitis. A symptom of importance in nasal disease of which the examiner should take cognizance is fetor. When pronounced, it is common both to the ozenal type of atrophic rhinitis and to the gummatous ulcerative or necrosing stage of nasal syphilis. To epitomize briefly the symptomatology of chronic nasal affections, one should observe the character and location of a nasal discharge with reference to sinus empyema; the degree and persistency of nasal obstruction with regard to neoplasms; and the presence of fetor and crust-formation with reference to syphilis, these being the diseases which materially influence life expectancy. Diseases of the larynx will bear a closer analysis as regards life expectancy, for this organ is a favorite site for obstructive conditions and for progressively fatal affections, such as tuberculosis and cancer.

Early Diagnosis of Pulmonary Tuberculosis.—Dr. Geo. W. Webster read this paper. He first described the clinical manifestations, including an examination of the sputum, and then the other means or methods which are available and valuable, such as the use of iodide of potassium, tuberculin, the X-ray, and the inoculation of animals. Reference was made at length to the family history, personal history, age, occupation, habits, previous illnesses, symptoms, general examination, mensuration, circulatory system, percussion, and auscultation. The earliest respiratory sign of beginning tuberculosis is enfeebled breath sounds, of a slightly roughened, harsh respiratory murmur, audible during expiration; or the expiratory sound slightly prolonged. This slight increase in the relative length of the expiratory murmur may be the only sign at first and may not have the slightest suspicion of a tubular quality, but is slightly increased in intensity. Auscultation of the voice is of great value in confirming the findings of percussion and auscultation. The X-ray has its advocates as a valuable means of early diagnosis, but the cost of the necessary apparatus, together with the high degree of technical skill required, will served to limit its value, which has not yet been satisfactorily determined. The iodide of potash test is one of very considerable value. In those cases in which there are very faint physical signs and an absence of even the amount of sputum for a microscopical examination, or where the physician desires to determine the location and extent of the tuberculous process, this method offers many advantages. The tuberculin test has warm advocates as well as strong opponents. The latter allege unreliability, reaction in other diseases, notably syphilis; no reaction in cases of undoubted tuberculosis. Its advocates assert that it is safe, delicate, reliable, and that in very many cases (and this applies perhaps with more force to tuberculous lesions, other than pulmonary) it furnishes an absolutely reliable and safe means of making an absolute diagnosis.

GENERAL.

Marine Hospital Surgeons.—President McKinley has recently nominated for promotion to full surgeonship in the Marine Hospital Service, Drs. Bell M. Woodward of Indiana; George T. Vaughn of Virginia; and Thomas B. Perry of Georgia.

New Jersey's Insane Asylum.—The appropriation of $54,000, recently made by the State Legislature, will enable the new wing for the reception of female patients, which is being erected at the State Hospital at Morris Plains, to be promptly completed.

Typhoid at Cape Nome.—It is reported from Cape Nome that typhoid fever has raged there during the winter. There have been 300 cases and 30 deaths. The colony of female nurses that has recently been organized for service in the mining camp is booked to sail very shortly for their destination. They will doubtless find plenty to do.

The Grip in Connecticut.—Connecticut is undergoing the most serious epidemic of grip that has visited the State in ten years. Dr. Lindsley, Secretary of the State Board of Health, stated on April 15th that the mortality during last March (1690) was unprecedented in any one month since January, 1892, when the total deaths numbered 1953, the highest that ever occurred in the State.

The Margaret Williamson Hospital.—This is the name of the hospital for the native women and children of China which has recently been completed at Shanghai under the auspices of the Woman's Missionary Society, whose headquarters is in the Bible House, New York City. This building replaces the one that was burned about a year ago. In the dispensary and in its wards, it cares for about 35,000 patients annually.

A New Spring at Bad Nauheim.—On March 7th a new effervescent thermal brine spring was struck in Bad Nauheim at a depth of about 700 feet. The water contains between three and four per cent. of chloride of sodium and has a temperature of 89° F.; it is also heavily charged with carbonic-acid gas. The fears formerly entertained that there might be a deficiency of such water at this resort have been banished by this new source of supply.

A Guide Book to Switzerland.—The Public Utility Association, Interlaken, Switzerland, has just published a little book of information for Americans who anticipate a trip abroad this summer. It is illustrated and gives information regarding transportation, hotel accommodations, etc. This will be mailed free to any one who will made application for it at the above address. Members of the profession who are planning to visit Switzerland may find this little book of great service.

Jamaica Ginger Drinking.—Four lumbermen in a Maine logging camp have recently died from drinking the contents of bottles labelled Jamaica ginger. The stomachs of two of these men have been examined at Bowdoin College, and as a result of the analysis made, the coroner's jury decided that death was caused in each instance by drinking a mixture purporting to be Jamaica ginger and so labelled. This "ginger" was found to be composed of alcohol and capsicum, flavored with a slight trace of ginger.

Professor Atwater on Alcohol.—Professor Atwater, of Wesleyan University, has recently reaffirmed his statement, based upon experiments scientifically conducted by means of the calorimeter, that alcohol has a limited nutritive value, mainly in the development of energy, being equivalent in this respect to fuel. He believes that total abstinence in respect to alcohol is the best course for all people in health, espcially young people.

Eddyism.—It is reported from Amsterdam that a wealthy widow of that city died recently of pneumonia under the care of a Christian science healer. It is alleged that the Christian scientists refused admittance to the patient to all but members of their faith until the case became hopeless, when physicians were called. An endeavor is being made to have the healer indicted by the grand jury. This case calls attention to the reckless and greedy quacks with this pretentious name who exercise neither knowledge nor discretion in applying their treatment.

The Plague.—The plague continues to rage with increased virulence in India. The famine-stricken people are also falling ready victims to various other diseases. There are now employed on the relief works of the famine districts of India over 4,800,000 persons. A few cases of plague were reported at Aden, on the Red Sea, March 17th. On the Island of Mauritius, for the week ending March 29th six fresh cases of plague and five deaths were reported. From Sydney it was officially reported April 15th that 111 cases and 38 deaths from bubonic plague had occurred up to that date.

Wounded Horses in Battle.—With a view to avoiding the suffering of wounded horses or mules on the field of battle, General Miles, during the recent Spanish-American war, issued an order that a veterinary surgeon, or some other person detailed by the commanding officer, should accompany troops in an engagement, whose duty it was to put an end to the agony of horses or mules that in his judgment were suffering to a degree requiring such action on his part. The British army in Africa has adopted the same practice.

Obituary.—Sir William Overend Priestly, Member of Parliament for the University of Edinburgh and St. Andrews since 1896 and formerly President of the Obstetrical Society of London, died recently in that city.—Dr. George H. Conklin, the oldest physician of Suffolk County, N. Y., died recently at Babylon at the age of eighty-nine.—Dr. Frank D. Kimball, twenty-four years of age, one of the house surgeons at the City Hospital on Blackwell's Island, died April 12th. The cause of his death was suppurative meningitis, complicating an attack of grip. Dr. Kimball was a graduate of Dartmouth Col-

lege and of the New York University Medical College.—Dr. J. S. Cocke, the blind physician of Boston, was recently found dead upon his bed with a bullet wound in the mouth. It has not yet been decided whether his death was due to foul play or to suicidal intent.—Dr. Charles C. Eastman, a leading insanity expert of New York State and assistant manager of the Binghamton State Hospital, died on April 11th. Dr. Eastman had been connected with the hospital since its opening in 1881.—Dr. Isaac C. Haring, one of the oldest physicians of Rockland County, N. Y., died in the Nyack Hospital on April 16th. He was a graduate of the Albany Medical College, and practised medicine in Rockland County for fifty years.—Dr. James Whitford, the oldest physician in Onondaga County, N. Y., died on April 16th. He practised medicine in Madison County for thirty-four years and for twenty years at Onondaga Valley, residing in the historic house which Joshua Forman, the pioneer of the Erie Canal, built more than a century ago.

Medical War News.—Investigation into the cause of the outbreak of typhoid fever among the Boer prisoners on board the prison ships at Simonstown, has revealed the fact that the drinking-water supply of the prison ships is taken from the same source as that from which the war-ships in the harbor are supplied. As the fever is confined to the Boer prisoners, it is manifest that it is due to infection acquired previous to imprisonment. The victims of the war are just beginning to appear at the clinics in London, and afford interesting material for illustrating lectures upon gunshot wounds. Our non-combatant profession has again sealed with its blood its devotion to the relief of suffering humanity in the person of Dr. C. Irvine, who attended the wounded for two hours under a terrible fire at Koorn Spruit until he was finally struck and instantly killed. By a strange coincidence he was struck by three bullets simultaneously. This may have been simply accidental, but it looks sadly like sudden concentration of fire on the part of a squad. This would seem to confirm Botha's statement that the surgeon who is doing his best to enable wounded men to return to duty in the shortest time is really a combatant, and not entitled to the immunities of the Red Cross.

American Gynecological Society.—The twenty-fifth annual meeting, semi-jubilee, will be held at Washington, D. C., May 1, 2, 3, 1900.—The following is the program:

1. The Technic of Operations for Intraligamentous Tumors, H. N. Wathen, Louisville, Ky.
2. Fecal Fistula, I. S. Stone, Washington.
3. A Study of the Remote Results of Conservative Operations on the Ovaries and Tubes, W. L. Burrage, Boston.
4. Internal Secretion of the Ovary, A. W. Johnstone, Cincinnati.
5. The Technic, Indications, and Ultimate Results of Suturing the Round Ligaments to the Vaginal Wall for Retroversions and Flexions of the Uterus, Hiram N. Vineberg, New York.
6. A Comparison of Vaginal and Abdominal Operations, G. Richelot, Paris, France.
7. Demonstration of Casts Illustrating the Anatomy of Pregnancy and Labor, also Models Used in Gynecologic Teaching, J. Clarence Webster, Chicago.
8. The Best Method of Removing Uterine Fibroids, Howard A. Kelly, Baltimore.
9. Combined Nephrectomy and Ureterectomy, E. E. Montgomery, Philadelphia.
10. Anastomosis of the Ureters with the Intestines; An Historical and Experimental Research, Reuben Peterson, Chicago.
11. A Critical Survey of Ureteral Implantation, J. W. Bovée, Washington.
12. Migrated Ovarian Tumors, George M. Edebohls, New York.
13. An Appreciation of Kelly's method of Removing Fibroids of the Uterus, A. Lapthorn Smith, Montreal.
14. Bronchial Disease not Invariably a Contraindication for Ether Anesthesia in Abdominal Surgery, Thaddeus A. Reamy, Cincinnati.
15. The Treatment of Full-Term Ectopic Gestation; Should not the Child Receive More Consideration? Edwin B. Cragin, New York.
16. The President's Address, George J. Engelmann, Boston.
17. The Relationship between Dysmenorrhea and Appendicitis, Archibald McLaren, St. Paul, Minn.
18. Clinical Data Relating to *(a)* Urinary Toxemia; *(b)* Operative Treatment of Uterine Displacements; *(c)* Ectopic Gestation; *(d)* Certain Complications of Uterine Fibroids, Egbert H. Grandin, New York.
19. *(a)* Demonstrating the Utility of a Certain Chart for the Determination of Pelvic Asymmetry from a Very Simple Method of External Pelvimetry. *(b)* Advantages of Employing a Certain Background in the Photography of Pathologic Specimens, Philander A. Harris, Paterson, N. J.
20. Contribution to the Management of Face Presentations, with Report of Two Cases, Malcolm McLean, New York.
21. Pernicious Nausea of Pregnancy, with a Report of Cases and Autopsy, E. P. Davis, Philadelphia.
22. Intra-abdominal Amputation of the Uterus, a Modification of Hysterectomy, F. H. Davenport, Boston.
23. A New Method of Operating per Vaginam for Carcinoma Uteri, also Applicable to Rectal Operations, William R. Pryor, New York.
24. Personal Reminiscences Associated with the Progress of Gynecology, T. Addis Emmet, New York.
25. The Status of Gynecology in 1876 and in 1900, Alexander J. C. Skene, Brooklyn, N. Y.
26. Reminiscences of the Foundation and Early Years of the Society, James R. Chadwick, Boston.

27. The Personal Factor in the Work of the American Gynecological Society, E. Van de Warker, Syracuse, N. Y.

28. Some Kaleidoscopic Pictures in Rhyme, Thaddeus A. Reamy, Cincinnati.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, April 7, 1900.

THE ROYAL FAMILY AND THE WOUNDED—THE WELSH HOSPITAL STAFF—SPLENDID RECORD OF HOSPITAL SHIPS—BOERS RESORT TO "EXPANSILE BULLETS"—MR. TREVES' HAPPY DISAPPOINTMENT—DR. THEODORE WILLIAMS HONORED—PROFESSOR NEISSER'S PAPER APPRECIATED—ST. GEORGE MIVART AND MEDICINE—DISSATISFACTION WITH MIDWIVES' BILL—LETTSONIAN LECTURES.

One curious effect of the war has been a great addition to the public social duties of the royal family, in the direction of visiting the wounded in their hospitals and in the inspection of the various hospital staffs. In one sense it is, of course, a pure formality and yet in another it is a graceful personal recognition of loyal service and patriotic devotion on behalf of the nation which it would be difficult to parallel under our colder republican forms.

This week a visit was paid by the Prince and Princess of Wales to a hospital in somewhat curious quarters, a suburban theater, which had been converted and lent for the purpose by the proprietor, Mr. Alfred Cooper. This is known as the Surbiton Princess of Wales' Home for convalescent soldiers and has already twenty-six inmates, to each of whom the Princess presented a pocket-book containing her photograph and a pocket-testament.

The same day the Prince and Princess received at Marlborough House the staff of the new Welsh Hospital, which is just ready to depart for the front. As might have been surmised from the fact that it is headed by a Thomas and contains two other members of the same illustrious patronymic, a Roberts, an Evans, while mention is made of a Boynmawr Jones, the entire staff is Welsh. It is to be presumed that the staple convalescent food at the hospital will be that appetizing and largely nutritious little rodent, the Welsh rabbit, in which case it will become the most popular refuge in the service, unless this be neutralized by permitting the staff to indulge in the sweet accents of their native tongue in the wards.

Both of these functions are typically significant of the patriotic generosity with which all classes of people are responding to the needs of the country in every conceivable way in this war. In spite of the large sums spent by the Government, the motto of the campaign ought to be the inscription across the front of most of the London hospitals, "Supported by Voluntary Contributions," so enormous has been the outpouring of private liberality and self-sacrifice for hospitals, ambulances, convalescent homes, transports, supplies, even troop and regimental equipments, guns, etc.

Of the eight hospital ships now lying in Durban Harbor, three are equipped entirely by private philanthropy, while two, if not three, of the remainder have been placed at the disposal of the Government by the companies owning them. These contain some 1,200 patients, and their efficiency may be estimated by the brilliant record of one of the largest, the "Nubia." Out of 674 cases discharged from the hospital from January 11th to March 10th, no less than 443 have returned to duty, and only 170 were sent on to Wynberg or Southampton as unfit for further duty.

The unanimity of all the medical reports from the front leaves little room for doubt that the Boers, as we ventured to predict some weeks ago, have become dissatisfied with this rapid recovery-rate and the ladylike character of the wounds made by the Mauser bullets and have resorted to less humane but more effective missiles. Nearly all recent descriptions of wounds comment upon their changed and much more serious character, and in almost every Boer trench captured are found the deadly and inhuman soft-nosed bullets, sometimes in packages carefully concealed and even buried, showing that the Boers know well that they are violating the rules of civilized warfare by using them. Mr. Treves even writes of finding "poisoned bullets," as the men term them, coated with a bright green composition which he thinks, however, is a harmless mixture of sulphate of copper and tallow, although he is bringing some home to be analyzed.

In nearly all of Mr. Treves' letters there is a suppressed but obvious undertone of almost pathetic regret at the small opportunities afforded in this campaign for abdominal surgery which, apart from patriotic motives, was his principal professional interest in going to the front. The reason for his disappointment is, however, a most happy one and one that he heartily rejoices in, *viz.*, the freedom from complications and rapid recovery-rate of abdominal wounds made by the Mauser bullet. It is a high tribute to Mr. Treves' conscientious humanity that he so promptly recognized the improved prognosis of these cases and at once threw the weight of his great opinion against the course which all his previous experience had led him to regard as advisable and along which his sole hope of really interesting and valuable professional experience in the campaign lay. One sentence in his last letter sums up the net result (speaking of a fearful penetrating wound of the abdomen), "Following the indications taught by this cam-

paign, I advised against operation; he made an excellent recovery."

A compliment has been paid the medical profession and a well-deserved honor bestowed by the election of Dr. C. Theodore Williams, well known for his work in pulmonary diseases in connection with the Brompton Hospital, as President of the Meteorological Society of Great Britain, in place of the celebrated Professor G. J. Symons, whose death occurred a few days ago. The honor is the more distinguished as this is the Jubilee Year and is being celebrated by various functions, including a visit to Greenwich Observatory and, of course, a dinner.

Much interest has been excited in the profession by the admirable paper of Professor Neisser in the Medical News, and this is aptly expressed by the long "leading article" (Anglice for "editorial") in a recent number of the *British Medical Journal*. Much of the doctrine advanced by the writer is comparatively new to the English practitioner and he is much impressed by the long vista of dangerous sequelæ of the common and hitherto lightly regarded gonorrhea opened up by it.

The medical world has a collateral interest in the death of the celebrated scientist, St. George Mivart, who died this week, in that he was both an M.D. and for many years lecturer upon zoology in St. Mary's Hospital Medical School. His "Lessons in Elementary Anatomy," although written many years ago, still remains one of the best introductions to zoology and comparative anatomy for the medical student. The circumstances of his death have also a philosophic interest for us as illustrating how hard superstition dies. Occurring as it did only a few weeks after his most intolerant denunciation as a heretic by Cardinal Vaughan, it is widely claimed by the faithful as a direct judgment of Providence, so that appeal was made to his family physician, who promptly testified that Dr. Mivart died of valvular heart-disease of long standing which had already brought him once to death's door and been a source of anxiety to his friends for two years past.

Grave dissatisfaction is expressed with the Midwives' Bill now before Parliament by the rank and file of the profession and indignant meetings are being held to protest against some of its provisions and the alleged apathy of certain members of the General Medical Council. The gist of the matter appears to be that under cover of a pretence to regulate and reform midwifery, the midwife is to be given a legal standing as a practitioner of a certain branch of medicine, independent of medical control or supervision, which she has never yet enjoyed in England. This the profession very properly resents.

Sir William Banks' admirable course of Lettsonian lectures upon cancer of the breast, delivered before the London Medical Society, closes in a more encouraging tone than is usual in discussions of late upon this gloomy subject. Although believing that the alleged increase of cancer is real and not merely apparent, and attributing it largely to over-feeding and the richer food-supply of recent years, our operative results have improved so vastly that the outlook for the future is distinctly more hopeful than before. He cites a characteristic series of 175 consecutive cases of cancer of various regions, operated upon in his own hospital, the Liverpool Infirmary, of which no less than 108 had remained free from recurrence, 75 of them for three years, 40 of these from three to six years, 28 of them from seven to fourteen years, 5 from sixteen to twenty-one years. A recovery-rate of nearly 65 per cent., which will be distinctly increased as earlier diagnosis and more radical removals are made, will help us to look with less distress upon a considerable rate of increase in the frequency of the dread disease itself.

SKIN AFFECTIONS IN BRIGHT'S DISEASE—RUPTURE OF THE ESOPHAGUS—NEW METHOD OF PERINEAL PROSTATECTOMY—SUGGESTION FOR THE TREATMENT OF GOUT—PREVENTION OF VALVULAR DISEASE IN ACUTE RHEUMATISM—REPORT ON THE FORCIBLE REDUCTION OF SPINAL DEFORMITY.

At the Royal Medical and Chirurgical Society, March 13th, H. Thursfield read a paper on the skin affections met with in Bright's disease. In the early stages of this disease are seen pruritus, urticaria and eczema; in the late stages and in uremic conditions universal erythematous, bullous or desquamative eruptions. Purpura and other hemorrhagic affections are rarely seen in Bright's disease, while the local affections which occur associated with extreme edema are simple local infections and entirely independent of the nephritic trouble. The occurrence of puritus in Bright's disease is well known, while urticaria has been less often referred to. He questioned the existence of a casual relation between the diseases of the kidneys and eczema, as there are no statistics to prove that eczema is more common in persons who are passing albuminous urine than it is in others. With reference to the eruptions of the late stages of Bright's disease, all writers have described an eruption consisting of papules and macules, which spread until the rash is confluent, and is followed by desquamation. This symptom is often the immediate precursor of uremic convulsions and, hence, is looked upon as a particularly unfavorable sign. A general bullous eruption occurring under similar circumstances, or a general desquamation, is less commonly met with. The most plausible explanation of various rashes is that they are due to some toxin circulating in the blood, and are therefore similar to the rash sometimes seen in septicemia, to the rash which follows the ingestion of

certain drugs. If such a toxin exists, its nature is unknown. It certainly is neither urea nor uric acid.

Pye-Smith said that the noticeable thing about eruptions in connection with kidney disease, is their rarity. In his experience the most common one consists of large discrete papules with considerable pruritus. He was not at all satisfied that eczema is ever due to Bright's disease. It can of course coexist with it. He put aside the purpuric conditions as only a part of the general tendency to hemorrhage.

At the meeting of this society held March 27th, R. L. Bowles and G. R. Turner related a case of rupture of the esophagus in a woman, aged sixty-two years, who had taken some aloes and rhubarb the previous night. The drugs purged her, as she intended, but they also set up violent vomiting. She then drank a glass of salt and water to clear her stomach, and in the vomiting thus brought about she collapsed and died twenty-two hours later. Before death there was emphysema of the neck, and the signs of pneumothorax were also present. At autopsy the rupture was found to be in the lower third of the esophagus, as has always been the case in those instances of this accident which have been hitherto recorded. Since the posterior mediastinum can be exposed without injury to any vital organ, the speakers advocated an operation on such lines, for all similar cases. If pneumothorax already exists, there is no especial need of avoiding the pleura.

At the Medical Society of London, March 12th, P. J. Freyer described a new method of performing perineal prostatectomy. The first step of the operation is the performance of external urethrotomy in the usual way. This permits of the passage of one finger into the bladder, by which, with another finger in the rectum, the surgeon is enabled to define accurately the shape, size, density and extent of the prostatic growth in a manner not possible by any other method, except, perhaps, a suprapubic cystotomy. By these same fingers the tumor can be pushed well into the wound so that its capsule can be incised, and the tumor shelled out or removed piecemeal. Moreover, the fingers act as a guide to the cutting instruments, so that it is possible to remove the whole of the growth and at the same time leave the mucous membrane covering it. A large perineal drainage-tube lessens the danger of sepsis. The operation is not suited to patients in whom the middle lobe is very much enlarged and projects into the cavity of the bladder. In very fat men, too, it is possible that the finger of the surgeon might not be long enough to reach above the growth so as to hook it down.

A. P. Luff read a paper on the gelatinous form of sodium biurate and its bearing on the treatment of gout, at the meeting of March 26th. He said that when first introduced into the blood, uric acid is in the form of a quadriurate of soda; that this is a very unstable body and is soon changed into the biurate, assuming first a gelatinous form and after that a crystalline form. While in the gelatinous form it is capable of elimination through the kidneys. When once in the crystalline form it is very insoluble, and is deposited as such in the tissues. This deposition is admitted by all to be associated with an attack of gout. Any treatment which will therefore delay or prevent the change from gelatinous to crystalline biurate will ward off an attack. By a series of experiments he determined that sodium salts accelerate the crystalline formation and so hasten an attack; that potassium salts delay not only the conversion of the gelatinous biurate into the crystalline form, but if the process is started they also delay its progress. Lysidine was found to possess the former of these attributes, and lithium the latter of them, but neither was as powerful as potassium salts. Piperazin had scarcely any effect. For this special purpose in the treatment of gout, the potassium salts rank first, and lithium salts and especially lithium carbonate come next; while lisidine and piperazin have scarcely any effect, and sodium salts are positively harmful. The author of the paper denied that an attack of gout is brought on by an excess of acid in the blood, affirming that the reverse is always true, namely, that the blood is more than normally alkaline when an attack occurs. He explained the presence or absence of pain as due to differences in the rapidity of deposition. When the crystals are deposited very rapidly there is pain.

At the Clinical Society of London, March 9th, R. Caton read a paper on the prevention of valvular disease in acute rheumatism, by a method which he has systematically followed during the last fifteen years with nearly 500 patients. They were put upon a light diet and given salicylates and cholagogues, and the following measures were also enforced: Absolute rest in bed for several weeks; the application of a series of small blisters, one at a time, each followed by a poultice in the course of the second, third and fourth dorsal nerves; sodium or potassium iodide in ten-grain doses three times a day. The object of the rest in bed was to protect as far as possible the softened valve-cusps. The object of the blisters was to stimulate the trophic nerves of the heart through the sensory filaments of the related skin area, and so to hasten repair and absorption, just as reparative processes are hastened by blistering the adjacent skin over an inflamed joint. The object of the iodides, to which mercury was sometimes added, was to help the absorption of the at first imperfectly organized inflammatory products in the cusps and endocardium. Caton believed this treatment to be of use only in the first two or three weeks. Fifty-four patients were admitted to the hospital with a bruit apparently of recent origin. Thirty-four of them left the hospital with hearts apparently sound, while twenty were believed to have valvular disease. Thirty patients developed

the first signs of valvular trouble in the hospital. Of these twenty-seven were discharged with hearts apparently sound, and three with valvular disease. He insisted that every case of acute rheumatism should be regarded not merely and essentially as rheumatism, which is comparatively unimportant, but first and before everything else as a case of impending peril to the heart, endangering the whole future life of the patient. Whenever the heart is sound at the outset the practitioner should examine it daily. If the above-mentioned means of treatment are persisted in for six weeks, the percentage of recoveries with sound hearts will be larger than by less careful methods of treatment.

R. Jones and A. H. Tubby made a report, March 23d, upon ninety-nine cases of forcible reduction of spinal deformity, the observations upon which the report was based having extended over a period of more than two years. Their conclusions were that the danger to life is not great; that far from inducing paraplegia, the operation is rather a curative measure; that abscess formation is less frequent; that the risk of disseminating tubercle is a negligible quantity; and that there is no risk of a flail-like spine. The contraindications are: Cervical and high dorsal curves, unless associated with paralysis; ankylosed spines; large and angular deformities; evidences of tubercle elsewhere; an age under two or over twenty-two years; and the presence of abscess, unless there is paraplegia. The object of the operation is not to obliterate all the prominence, but to give as erect a position as possible. The after-treatment demands constant personal attention, and an abundance of fresh air, and it should be continued for a period of three years.

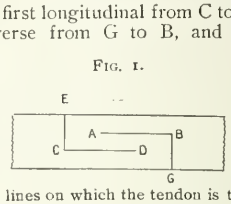
SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE—SECTION ON ORTHOPEDIC SURGERY.

Stated Meeting, Held March 16, 1900.
A. B. Judson, M.D., Chairman.

Lengthening the Tendo Achillis.—Dr. R. A. Hibbs presented five patients affected with talipes equino-varus, the result of infantile paralysis, on whom he had performed a new operation, as follows: The tendo Achillis, having been exposed by a parallel incision 1½ inches in length, made to its outer side, was cut transversely within ½ inch of its insertion, through two-thirds of its substance, and, with the turned knife, it was then split upward a certain distance. A quarter of an inch above the end of the longitudinal cut another transverse cut was made from the opposite side through two-thirds of the substance of the tendon, and, the knife being turned, the tendon was again split to within ¼ inch of the first transverse incision. Thus, the tendon was severed in such a manner as to secure its lengthening and at the same time to preserve its continuity. In Figure 1 the first transverse cut would be from E to C, the first longitudinal from C to D, the second transverse from G to B, and the second

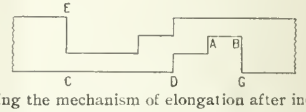
Fig. 1.



Showing the lines on which the tendon is to be incised.

longitudinal from B to A. When traction was applied lengthening would occur as shown in Figure 2 and it would be equal to the sum of the two longitudinal cuts minus the sum of the

Fig. 2.



Showing the mechanism of elongation after incision.

two laps of ¼ inch each. In Figure 1 if C D is ½ inch, B A ½ inch, A to E C ¼ inch, and D to G B ¼ inch, then the lengthening would be ½ inch plus ½ inch minus ¼ inch plus ¼ inch, or 1 inch minus ½ inch, or ½ inch. It is a matter of choice whether the longitudinal or the transverse cuts be made first, but it is important that the skin incision should be to the outer side of the tendon in order to prevent the scar from falling directly over the tendon, which might be rubbed by the shoe. Dr. Hibbs has learned since operating by this method that it has been practised in a case of traumatic equinus by Sporon, a Dane (*Hospitals tidende*, 3d series, Vol. IX., No. 50, 1891).

Case I.—In a girl 8 years old, a short tendo Achillis had prevented flexion of the right foot within 10 degees from a right angle. It was lengthened by this method on September 22, 1899, and the foot was fixed at a right angle. In two weeks slight voluntary motion was allowed and the muscle received daily exercise with some resistance from the attendant. After ½ inch lengthening had been secured there was positive resistance to any further flexion of the foot than was allowed by the lengthening. The child walked with strong control of the os calcis.

Case II.—In a girl 12 years old flexion of the left foot was impossible within 15 degrees from a right angle. The tendon was lengthened ¾ inch on July 6, 1899. With suitable after treatment the result was an excellent position of the foot with strong action of the muscles of the calf.

Case III.—In a girl 14 years old flexion of the right foot was prevented within 10 degrees from a right angle. The tendon was lengthened 1¼ inch on June 16, 1899, an unusual amount in order to relieve extreme valgus, with resulting

good control of the os calcis. As the valgus was recurring a tendon grafting would be done.

Case IV.—In a girl 8 years old the left foot was inflexible within 45 degrees from a right angle, appearing to be almost in a straight line with the leg. The tendon was lengthened 1¾ inch on June 16, 1899, and the foot fixed at a right angle. It was believed that an ordinary tenotomy would have been followed by loss of usefulness of the calf-muscles. It was seen, however, that this action was excellent.

Case V.—In a girl 14 years old the right foot had been inflexible within 15 degrees from the right angle and the tendon was lengthened ¾ inch on June 16, 1899, and the foot fixed at 90 degrees. The muscle and tendon showed enough strength to sustain the weight of the body on tip-toe and this had been true of all the cases presented. In no case had an effort been made to correct the equinus beyond a right angle. Further correction might be desirable in congenital, but not in acquired equinus.

That the strength of a tendon lengthened in this way is not seriously impaired is proved by the observation that in every case there had been resistance to the carrying of the flexion beyond the limit allowed by the operation and also by the ability of the muscle and tendon to sustain the body on tip-toe. The process of repair had been rapidly completed after operation by this method, which presented obvious advantages over those in which sutures were applied to the tendon. But the greatest advantage had been found in the readiness and certainty with which the desired amount of lengthening could be exactly secured.

A perfect gait required the "spring" or elastic quality imparted by the muscles which enabled the anterior part of the foot to sustain the weight of the body in walking. Without this power the gait would be that of one who had a wooden foot or a foot affected with talipes calcaneus. In equinus following infantile paralysis it is probable that the muscles are more shortened than the tendon and, as lengthening the muscles is generally impossible, operative relief has to be sought by lengthening the tendon. In operating, however, it is important, on the one hand, to avoid leaving the tendon so long as to impair the action of the muscle, and, on the other hand, to avoid leaving it so short that the equinus will not be sufficiently overcome. This method enables the operator to maintain exactly the proper relation between the length of the tendon and that of the muscle. By subcutaneous tenotomy the equinus is readily corrected, but in many cases the result is a serious defect in the gait from undue lengthening of the tendon and resulting shortening and inefficiency of the muscle.

Dr. A. M. Phelps said that it is immaterial whether a muscle is operating at its full length or whether the same amount of muscle tissue is operating at a shorter leverage. The power is precisely the same, as instanced by putting the arm nearly straight or flexing it. So long as the amount of muscle-cells remain, the power is the same. Open incisions for primary operations on the tendons should be avoided, and in the ordinary subcutaneous operation the tendo Achillis should be made too long, if possible, by overcorrecting, the normal process of repair being relied on to fill in the space between the ends and to secure an accurate and efficient adjustment of the relative lengths of the structures. He has repeatedly seen 4 inches replaced after the division of the tendo Achillis and perfect function of the muscle restored.

Dr. Hibbs said that an alteration in the relative length of the muscle and its tendon modifies the effect of muscular contraction. If the tendo Achillis is lengthened the contractile power of the muscle-cells may remain, but the extent to which the os calcis can be raised by the contraction of the muscle will be lessened. If the muscles of the calf can not momentarily sustain the weight of the body on tip-toe in the act of walking, they are not of great use.

Dr. H. L. Taylor said the fear of impairment of function after ordinary tenotomy properly done and followed up is unnecessary. It was formerly the custom after division of the tendon to put the foot up in the deformed position and to correct the deformity at subsequent sittings. Correcting the deformity immediately after the operation is attended with good results. It is possible to elongate the tendon too much, but such cases were rare. He has been looking for years for a case of ununited tendon after tenotomy, but has not found one. The exact amount of correction would vary with the kind of case. It is a matter of judgment. The results in the patients shown are admirable.

Dr. H. Gibney said that he has seen one or two adults in whom the tendons had failed to unite. He can see no advantage in the new operation over the ordinary subcutaneous method, after which many cases acquire a length of 2½ inches. The results shown, however, are excellent and will be better still after the tenderness and indisposition to voluntary motion have worn off.

Dr. J. P. Fiske said that the results shown are good and that the details of the new operation are very interesting. It is, however, a departure from the rule of simplicity that characterized the old operation which, almost without exception, gave results and left nothing to be desired.

Dr. A. B. Judson admired the mechanical ingenuity displayed in the operation. A short tendo Achillis produces no deformity and does not interfere with the normal gait, excepting in cases in which the tendon is extremely short. Normal flexion of the ankle may be said to be about 40 degrees within a right angle, but with 10 degrees the gait is normal in appearance and ability and the patient experiences no inconvenience, even when assuming the unusual position of squatting. In measuring the equinus it is desirable to have the leg flexed on the thigh in order to relax the gastrocnemei which have their origin in the femur. The foot being held

flexed manually, so far as it can be done painlessly, one arm of the goniometer may be made parallel with the crest of the tibia and the other parallel with the inferior surfaces of the os calcis and the head of the first metatarsal bone. The degrees can then be read on the scale. In the use of the club-foot brace for congenital equinovarus, setting the upright backward from a right angle lengthens the tendo Achillis, which is contrary to what might have been expected. The object of setting it backward is to increase the leverage applied for the reduction of the varus. Lengthening of the tendon follows this adjustment in every case.

Dr. Taylor a few years ago offered an explanation of this action of the club-foot brace by the theory that, as the inner border of the tendo Achillis is shorter than the outer border, when the foot is rotated outward by the brace, the inner border is first put on the stretch and gives way, fiber after fiber, thus unexpectedly lengthening the whole tendon.

Dr. Hibbs said that he has operated in this manner on more than twenty patients, but those presented are the only cases in which sufficient time has elapsed to make the presentation useful. It is vastly more important to preserve the action of the muscles than to relieve the deformity, which is generally not serious and in some cases is absent.

THE CHICAGO MEDICAL SOCIETY.

Stated Meeting, Held March 14, 1900.

Gynecology and Surgery Abroad.—Dr. Albert Goldspohn read a paper in which he narrated his gynecological and surgical observations during a recent trip to Europe. He directed attention to the views and the practice of prominent operators in Europe with reference to subjects upon which opinions differ, and to the practical bearing of some of the original researches in this field, as far as he became cognizant of them from participating in the proceedings of the International Gynecological Congress at Amsterdam and of the Gynecological and Surgical Sections of the German Naturalists' Association at Munich, and from seeing a score of German and Austrian operators at work in their individual institutions.

Permanent Non-Progressive Sequential Ataxy.—Dr. Sanger Brown read a paper on this subject in which he reported three cases. He described as minutely as possible the primary illness to which the ataxy was secondary in each case. He said that the cases, from the clinical side, had much in common, presenting more or less severe acute and probably infectious symptoms of varying duration and character, which resulted in profound general muscular ataxy, showing itself conspicuously in the muscles concerned in articulate speech. In none was there any lasting impairment of special sense or of general sensation. The ataxy has been essentially stationary; the general health has been excellent after the primary acute illness subsided and the mental condition is normal. In Cases I. and II. the residual symptoms are very similar, almost identical throughout, while in Case III. there remained other prominent symptoms besides ataxy. The essential question in the opinion of the writer is, what part or parts of the normal adult brain have to be injured in order that ataxy shall result?

Experiments on the lower animals, studies in embryology, and clinical and post-mortem observations on the human subject have abundantly demonstrated definite relations between the neurons of the cerebellum and those of other parts of the nervous system, both sensory and motor. Assuming that the cerebellum exercises a predominating influence upon the coördination of voluntary muscular movements, then, it would not be unreasonable to assume in the cases cited that one effect of the primary disease had been in two of the cases to permanently injure those parts of the organ subserving this function, or, what would amount to the same thing, a considerable number of the neuron processes connecting it with other parts of the nervous system. Excepting in the cerebellum or its peduncles, these connecting fibers are so intimately related to, and intermingled with, other structures that it is difficult to conceive of any acute pathological process that might severely injure or destroy them without also injuring the others, thus giving rise to other permanent symptoms. And yet it is hardly more difficult to conceive that a toxin might limit itself, say, to the cells of Clark's column, which are believed to send their processes to the cerebellum, forming the so-called direct cerebellar tract, thus connecting it with the sensory nervous system, than to understand why in certain cases only the bodies of the peripheral motor neurons should be attacked, as in anterior poliomyelitis.

The condition of the muscular system, especially in Cases I. and II., was very similar to that of one of the well-marked and advanced cases of hereditary ataxy in the series reported by him several years ago.

If it is conceded that the influence of the cerebellum is paramount in controlling muscular coördination, when the position and extent of the various tracts are remembered which connect it with other parts of the nervous system, it is not difficult to understand how far apart pathological processes might be situated, and yet by destruction of one of these connecting paths throw the cerebellum out of the circuit, so to speak, and thus give rise to ataxy. In many cases of the progressive types of ataxy, as locomotor ataxy and the so-called hereditary ataxies, the pathological process apparently begins and is for a long time confined to the spinal cord, while in the cases described it was apparently in the brain.

Dr. Brown said that the mere clinical report of such cases by itself was of little value in helping to locate the center or centers in the brain

which control muscular coördination, or the relation of these centers with other parts of the nervous system; but if the cases could be brought to autopsy they might go a long way in that direction. His main purpose in describing them is founded on the hope that in the end, if enough similar cases are recognized, autopsies may be obtained which will render valuable contributions to a subject resting at the present time in considerable obscurity. A not very exhaustive examination of available literature has revealed several reports of cases similar in some respects to those of his. They have been variously designated as acute ataxy, bulbar ataxy, the symptom complex of Friedreich's ataxy—all following acute infectious diseases. In none, however, so far as he is aware, has the ataxy alone been of long standing, if, indeed, it has yet become stationary.

Ankylosis of the Stirrup.—Dr. J. Holinger read a paper on this subject. He said the condition is comparatively frequent, and leaves the patient utterly hopeless. The pathology has been studied by Professor Lieberman, and was given by the essayist in a paper read before the Chicago Pathological Society. The otologist is able to make an accurate diagnosis with the aid of functional tests. The treatment is unsatisfactory; the prognosis unfavorable. The number of cases in which post-mortem examinations have verified the diagnosis of this disease in the living is increasing year by year.

Meeting of March 28, 1900.

Some Therapeutic Observations.—Dr. William T. Belfield read a paper on this subject in which he considered the hemostatic properties of gelatin. After referring to the experimental work of Dastre and Floresco in 1896, he reviewed the Lancereaux treatment of aneurism by subcutaneous injections of gelatin, and proceeded to a discussion of this agent as a styptic and hemostatic. As a styptic, gelatin has earned a foremost place since it seems never to have failed when applied in ten- to twenty-five per-cent. solutions to arrest bleeding, even when the usual styptics had failed. Among the cases in which it has been tried were wounds, including one in a case of hemophilia, bleeding from the nose, stomach and uterus. The value of gelatin as a hemostatic has yet to be accurately determined. The literature of this subject is exceedingly scanty, a few cases reported by Bauermaster alone being available. These were invariably successful. The reader added reports of three cases in which subcutaneous injections of gelatin had been used to arrest hemorrhage in essential renal hematuria, malignant disease of the bladder, and malignant typhoid fever respectively. In the first two cases bleeding was promptly and permanently arrested. In the third no appreciable effect was produced. Bauermaster's observation, that in a case of chronic parenchymatous nephritis the use of gelatin was followed in two days by fatal uremia, led the reader to the experimental injection of two guinea-pigs with relatively enormous doses of gelatin solution. One of these seemed unaffected, while the other, when killed, showed congested kidneys. It would seem that existing chronic nephritis should contraindicate the use of gelatin.

Syphilis of the Female Breast.—Some years ago the author removed a woman's breast for what seemed to be a typical carcinoma. A year later manifestations of late syphilis led to inquiries, which revealed a clear history of syphilis in the patient nineteen years earlier, together with other manifestations of late syphilis. This patient showed a tumor of the remaining breast which closely simulated carcinoma, but which disappeared completely under the usual treatment for syphilis. It seems extremely probable that the tumor removed a year previous was a syphiloma of the breast. Another patient applied for treatment of gumma of the leg. A year before this patient had had a tumor of the breast with enlarged axillary glands. The breast had been removed by an experienced surgeon. The glands, which were not removed, quickly diminished in size after the operation. The patient's husband admitted syphilis sixteen years before. This, like the first case, seems to have been a syphiloma of the breast, but was mistaken for a carcinoma.

Primary Keloid.—A growth of this kind in a young woman was partly healed by the internal administration of thiosinamin. The remainder of the growth resisted the action of this drug. It was quickly removed by injections into the keloid of a twenty-five-per-cent. resorcin solution after infiltration anesthesia. Several weeks later the injected tissues sloughed off, leaving a thin, white natural scar. The cure has lasted two years.

Roentgen Rays for Removal of Hair.—Dr. Wm. Allen Pusey read a paper on this subject in which he considered the effects of Roentgen rays upon the tissues in general and reviewed the work done in this field up to the present time. The effects of X-rays upon the skin and subcutaneous tissues which suggested their use for therapeutic purposes are: (1) Changes in the epidermis itself or in its appendages. In a general way, these consists of hyperplasia of the least differentiated elements of the epidermis and atrophy of the highly differentiated elements as shown by blanching of the hair; out-fall of the hair, and trophic changes in the nails similar to those in the hair, sometimes resulting in interference with growth and in severer cases in shedding of the nails. (2) Changes in the corium and subcutaneous tissues which are all inflammatory in character. Of these effects of X-rays, the two which offer prospects of the utilization for therapeutic purposes are, first, its power of causing falling out of hair, and, second, its power of reducing inflammatory reaction and in influencing the nutrition of the tissues.

The method has been applied chiefly in four classes of affections: (*a*) In hypertrichosis, for the removal of undesirable hair. (*b*) In mycotic

affections of the hair and hair-follicles, such as sycosis, tinea tonsurans, favus, where the removal of the diseased hair is an essential part of the treatment. (*c*) In the treatment of inflammatory affections, like chronic eczema, where the purpose is to stimulate the tissues and cause absorption of inflammatory products. (*d*) In certain specific affections, like lupus, where it is desired to cause destruction or absorption of tissues of low vitality.

Experience thus far demonstrates that in some cases the hair can be permanently removed by the use of X-rays and without damage to the tissues, and it is believed that the method will be found practical and efficacious for the treatment of cosmetic defects due to superfluous hair. The method has proved useful in deep-seated intractable cases of sycosis, and has also been successful both in tinea tonsurans and favus.

Its use in eczema does not seem to offer particular advantages over other methods of stimulating treatment, although in certain persistent thickened patches of chronic eczema it may have a field of usefulness.

Its most important field of usefulness perhaps will be in the treatment of lupus. Testimony to its efficacy in lupus comes from many quarters, and there is every reason to believe that it is a most valuable remedy in the treatment of this affection. The advantages it offers for the treatment of lupus are summarized as follows: (1) Efficacy; practically all of the cases which have been cured by this method have been of grave persistent character and had resisted for years recognized forms of treatment. (2) Freedom from pain of the treatment. (3) The character of the scars. All observers agree as to the excellent character of the scars following this method of treatment. They are soft, pliable and thin, and nearly approach the normal skin in appearance. The treatment of lupus by the use of X-rays is undoubtedly the same in principle as the treatment devised by Finsen by the ultra-violet rays of white light, one method consisting of using actinic rays of high value which are found among X-rays, the other using the actinic rays found at the violet end of the spectrum of white light. The method has been tried in various other affections in addition to those mentioned, but with what results it is still impossible to say. There is no ground for believing that the method will prove a panacea for skin diseases.

AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY.

Meeting of the Southern Section, Held at Galt House, Louisville, Ky., March 30, 1900.

The address of welcome was delivered in a few well-chosen words by Dr. S. G. Dabney of Louisville, and was fittingly responded to by Dr. L. B. Graddy of Nashville.

Dr. J. A. Stuckey of Lexington, Ky., the efficient chairman of the Southern Section, then addressed the meeting in his characteristic manner. He said that although the organization had been effected only five years ago, its membership was now more than two hundred, actually engaged in the practice of these particular branches. He directed attention to the rapid progress that had been made in recent years in the explorations of the cavities of the nose and throat, reviewing step by step the introduction of cocaine and anesthesia, the use of illumination of cavities and the possibility of doing bloodless operations by means of the suprarenal extract. The use of ointments, powders and douches is now of questionable utility and the atomizer fiend is falling in line with the hypodermic fiend. He called attention to the fact that the laryngologist now removes the larynx and the patient not only lives but talks; the otologist chisels away portions of the skull and the patient not only lives but hears; the rhinologist makes the nasal passage as smooth as a gun-barrel and the patient not only lives but snorts. All this progress has been freely given to the public and the physician has made himself the servant of the profession; there is no longer any clash between the specialist and the general practitioner.

Dr. Hanua W. Loeb of St. Louis presented the first paper, its title being "One Hundred and Seven Polypi Removed at One Sitting, with Remarks as to the Value of the Electrocautery Snare in Removal of Polypi." The case was that of a negro man in the City Hospital who had been operated on for sarcoma of the orbit with removal of left eye. The patient was very weak at the time of operation, which was completed at one sitting. Sixty-eight pieces were removed from the one side and 59 from the other; eliminating 20 of these, there remained 107 well-formed polypi, which Dr. Loeb exhibited. Their weight was 77 grains and they would about fill a two-ounce bottle.

Dr. Loeb used the snare for the reason that it enabled him to remove all at one sitting, because of the freedom from ordinary electrocautery snare in that the wire did not pass entirely through the cannula but was more easily threaded. The patient had some recurrence but left the hospital and has not since been located.

Dr. Norval H. Pierce of Chicago thought the operation would have been impossible with any other form of snare, because of the profuseness of the hemorrhage with the cold snare in removal of tumors. He thought an improvement could be made in the shaft of the snare used.

Dr. Thompson of Cincinnati mentioned a case of a patient with two very large polypi, one being 2½ inches long and ¾ inch in diameter; the other 1¼ inches in length and ¾ in diameter. One feature of it was a constant headache for fifteen years which never left the patient during her waking hours, due to supra-orbital neuralgia.

Dr. S. G. Dabney of Louisville reported a case of a fibroid-mucous polypus which caused constant vomiting. It was removed with the electrocautery snare, with no subsequent trouble.

Dr. Stucky mentioned a case operated on eight years before. The nose was two and a half inches at the base, turbinates absorbed, cartilaginous septum gone. The polypi were removed at three or four sittings with the cold snare and curette. The antrum was full of them and the ethmoid had to be curetted. He has operated twice since then, but during the last two years has had no reported recurrence. A twenty-five-per-cent. chromic-acid solution was used last time with alarming gastric and nervous symptoms, with septic symptoms continuing for several days.

Dr. Loeb, in closing the discussion, said that in eight years of almost exclusive use of the electrocautery snare he had seen practically no secondary hemorrhage. He attributed much of this success to the cleanliness of his instrument. As to the recurrence of the polypi after the use of the electrocautery snare he was not so enthusiastic as in earlier years, but still believed that its possibility was greatly lessened by the use of the electrocautery. There was a recurrence in the case under discussion, but the man had not been found and no definite report could be given.

Dr. Norval H. Pierce of Chicago then presented a paper on the "Treatment of Peritonsillar Abscess, with Exhibition of New Instruments." The chief objects of the paper were to accentuate the proper place for incision and to present instruments to meet the indication. Nothing is more annoying than an unsuccessful attempt to reach the pus and nothing more gratifying than its removal, which was nearly always curative. Early incision is not only justifiable but indicated, for they do not always rupture spontaneously. He referred to the fact that most authorities recommended incision at the point of bulging, generally at the upper anterior surface of the anterior pillar, 5 cm. from its edge. This bulging is not always due to pus but may be from edema or from the tonsil itself. Spontaneous rupture takes place through the anterior pillar and that by far the most frequent place is the fossa supratonsillaris and this is the proper place for incision. This fossa may be best seen by pulling out the tongue, depressing its dorsum with a spatula, pushing outward the opposite corner of the mouth, and inclining the head to the opposite shoulder. This fossa as situated between the anterior and posterior palatal arches and above the tonsils; its opening is triangular, the base formed by the tonsil and the anterior and posterior borders by the pillars of the fauces. It extends inward, upward and outward into the soft palate, downward and anteriorly between the tonsil and plica triangularis and sends prolongations downward for a variable distance behind the tonsil. The abscess may begin in the upper or palatal portion or even behind the tonsil; wherever it might be, it could be best reached by incision at a point between the anterior and posterior pillars; this was the emphatic point of the paper.

Dr. Pierce then exhibited certain instruments devised by him for reaching this abscess, one of which was a knife with blade at right angles to the shaft, cutting edges anteriorly and posteriorly. This, to be used when the mucosa is too dense for the forceps, was also exhibited. With these latter the incision is ordinarily to be made, using them as in blunt dissection.

Dr. Loeb opened the discussion by confessing that he had been trusting to luck in these operations and that he had been frequently disappointed by failure to find the pus at point of bulging. He intended to work on the fossa supratonsillaris hereafter.

Dr. Cheatham also confessed to frequent disappointments and failure to find pus. He had never opened at the supratonsillar fossa. The abscesses pointing posteriorly had given him the most trouble.

Dr. Cochran said that his patients had been unable to open their mouth to any great extent and that he usually employs a syringe with very hot water until the parts relax. He then opens at the point of bulging with a straight or partially curved knife.

"Acute Thyroiditis" was the title of a paper presented by Dr. D. Bradon Kyle of Philadelphia. He had seen two cases within two weeks, the only ones he had ever seen, and in reviewing the literature of this trouble emphasized the rarity of this condition. There are two forms, suppurative and simple. The latter form is more common in females between twenty and thirty years of age; sudden onset, vague pains in the neck, swelling of thyroid to size of a hen's egg, marked fever; swelling and fever begin to abate in three or four days. The suppurative form occurs in septic diseases, has a characteristic fever and general symptoms and local signs of suppuration. There is often an infection of bacterial origin, but most frequently the causal factor has not been located.

Like the suprarenal tissue the gland has no duct, three lobes with the middle lobe dwindled down to an isthmus, the secretion removed by the lymphatics of the glands and those surrounding it. Its function is problematical, inert in growth but necessary to the maintainance of health, functional activity greater in youth; rise of temperature after removal, blood becomes fibrous with a diminished function of the red blood-corpuscles similar to the change that takes place in pneumonia. Inflammation interferes with the manufacture and taking up of the colloid substances and goitre results oftentimes. Acute thyroiditis may occur in an already enlarged gland.

One or more lobes may be involved, rarely middle, may end in suppuration; irregular temperature, chills, edema of larynx and pharyngeal structures. The enlargement causes difficult swallowing, fever like that of typhoid, severe and depressing headache, vertigo and perhaps cyanosis.

Two cases were reported with recovery in both. The treatment was the administration of calomel for several days, salines, and cold continuously with ten minutes intermission each half-hour, and stimulating nourishment.

Dr. Jos. A. White of Richmond, Va., reported

a case, the only one he had ever seen, occurring fifteen years ago. There was a swelling the size of a hen's egg over the trachea. Application of a blister of red iodide of mercury and iodide of potash in vaseline, which vesicates quicker than cantharides, gave quick relief. Dyspnea was a prominent symptom in this case and all symptoms were relieved in two or three days. Dr. Thompson of Cincinnati called attention to the possible difficulty in diagnosis, a suppurating brachial cyst simulating it very much. Dr. M. F. Coomes of Louisville, reported a case which had occurred in his practice in the '70's in which dyspnea had been a pronounced symptom and in whom a large goitre developed later. Dr. Kyle, in closing, stated that the function of the thyroid gland is problematical but it has considerable to do with health. Its vascularity is like that of a sarcoma. A goitre can be traced often to an acute inflammation of the gland. In a series of cases at the Jefferson Medical Hospital, reaching from forty to seventy-five a day, there had not been but the two cases reported.

The afternoon session was opened by Dr. J. A. White of Richmond, Va., who reported a case of death in four days following a simple operation for nasal synechiæ and inquired whether the death was a sequence or coincidence. The case was that of a young man presenting himself on December 8th with symptoms of constant headache, nasal obstruction and hyperoptic astigmatism. Dr. White first corrected the astigmatism and then broke up the adhesions of the deflected septum. After a few days the headache returned, but was less severe and there was still some nasal obstruction. A little chromic acid was then used. On the 23d he was looking very badly but nothing out of the ordinary was found. The temperature was 103.3° F., but under quinine came down readily. The next day he was found unconscious at the hotel, having been sitting in the same place for sixteen hours. Temperature was 101, pulse 90, slight contraction of the tendons of the left hand; no eye symptoms. All efforts to arouse him failed. Eight ounces of urine were drawn and found to be almost solid albumen. Dr. White at once thought of meningitis and of uremic poisoning; as to the former, he had never heard of a case of nasal traumatism or inflammation of the ethmoid cells or frontal sinuses non-purulent in character having been the cause of meningitis. He did not think it could have been a thrombosis and was inclined to the belief that his death was due to nephritis. He thought the rapidity of the man's death precluded meningitis. No autopsy was permitted. Dr. White admitted that simple operations upon the nose are very often followed by consequences out of all proportions to the traumatism, but did not believe that this was the cause of the man's death.

Dr. Kyle thought Dr. White was right in ascribing death to kidney lesion; it was either that or thrombosis, in his opinion.

Dr. Graddy had had no similar experience, but agreed that it was a case of advanced albuminuria.

Dr. Pierce also expressed himself confident that it was a case of chronic nephritis. He called attention to the apparent intimate connection between albuminuria and nasal operations, mentioning the case of a young man meeting with a nasal traumatism who developed a serious condition of albummuria, yet whose urine had been examined for life insurance three days before the accident. He reported another case where the application of chromic acid increased the albumen to an alarming extent.

Dr. Cheatham did not think Dr. White's operation had anything to do with the death of the patient. He emphasized the occurrence of serious symptoms occasionally from the most trivial operations on the nose, illustrating it by the case of a patient who rapidly developed erysipelas after a trifling operation. He did not believe in predisposition playing a part in these troubles and said that the only predisposition he believed in was an abrasion of the nose.

Dr. White closed the discussion and expressed his disappointment at not receiving more information regarding the relation of the operation to meningitis. He was anxious to know if it would be possible for meningitis to have fully developed in such a short time without previous suppuration in the nose. He was fully aware of the dangers following nasal operations and said that it was his invariable rule to take the temperature the next day. He had seen violent attacks of tonsillitis follow within twenty-four hours, but had never been able to determine the connection between the two. He thought the erysipelas in the case reported by Dr. Cheatham came too quickly to have been due to the operation, yet he had seen cases where there seemed to be connection.

Dr. T. V. Fitzpatrick of Cincinnati, O., presented a paper entitled "Nasal Angioma." He reported the case of a woman, twenty years of age, with no nasal injury or disease. There had been hemorrhages for six months; not much obstruction to respiration; pulsation in nose; the tumor was attached to inferior turbinate with a slough on its anterior surface. The case was reported as the literature on the subject showed true angiomata to be rare. Dr. D. B. Kyle stated he believed these tumors to be a dilatation of the original blood-vessels. The tumor referred to in literature is a mixed tumor spoken of as a fibro-angioma or other combination. If it is a true blood-vessel tumor it is not a new growth; it is benign. Dr. N. H. Pierce said one is apt to confound the growths mentioned by the essayist with growths on the vascular turbinates. He referred to two cases in whom there was recurrent hemorrhage; in one the tumor was the size of a pin, in the other it was as large as a pea.

Dr. M. F. Coomes of Louisville, presented a clinical case of angio-fibroma of the nose and pharynx. When first seen the patient was exsanguine, a mass protruded from the mouth and nose, and a piece hung in the larynx interfering with his breathing, and the tongue was concave to accommodate the growth in his mouth. The

greater part of the mass that could be reached was removed piecemeal by snaring, cutting and ligating. A Jarvis snare was pushed back on the growth, tightly applied and left on from 60 to 120 hours, then punctured and removed. The patient recovered but has still a large mass showing externally.

Dr. Joseph White of Richmond stated that it is impossible to entirely eradicate a fibroma; it will recur. Cases that are considered cured generally go elsewhere after a recurrence takes place and the original observer has classed it as a non-recurrence. Several cases of fibroma of the orbit observed by the speaker all had recurred. Dr. Coomes states his experience with fibromas was the same. They do recur. A cautery should not be used in these cases, it has no effect on the hemorrhage. The prognosis in the case presented is of course bad.

Dr. T. V. Fitzpatrick of Cincinnati reported a case of persistent nasal hemorrhage which had given him a great deal of worry. It followed the removal of a hypertrophied turbinate upon the right side with the galvanocautery. It is his custom always to ask a patient before a cutting operation if he has been a bleeder, and this one had stated he bled freely ten years ago but since that time had not. Two days after the operation he was found to be bleeding profusely, almost exsanguinated. This was controlled by a gauze packing, but after the second packing the bleeding occurred around it, due, he believed, to a subsidence of the swelling of the vessels and consequent loosening of the packing. A general pulsation all over the body was felt before each attack of hemorrhage. This vasomotor disturbance was seen to precede each hemorrhage. A hypodermic injection of ergotin given by the nurse caused dizziness, faintness and convulsive body-movements lasting fifteen minutes. Thirty-grain doses of bromide of sodium were given with a disappearance of the vasomotor disturbances and bleeding. The packing was removed without recurrence of bleeding. Dr. Dudley S. Reynolds of Louisville stated he had had good results from the use of suprarenal extract in a case of obstinate nasal hemorrhage in a patient not operated upon. A solution of dry suprarenal extract, macerated in one ounce of hot sterile water and ten grains of boric acid added after two hours, the whole being filtered. Application was made in this case with a mop of cotton to the whole septum which was bleeding. The same application proved effectual in this patient after an obstinate recurrence. He commended the use of suprarenal extract for obstinate and troublesome hemorrhage.

Dr. S. G. Dabney of Louisville stated that all had been delighted with the use of the suprarenal extract to prevent hemorrhage during an operation, but he did not think the results had shown it to be so successful in stopping a hemorrhage when it had once begun. Dr. J. A. White said he preferred a hemorrhage at the time he was operating and not afterward. The use of the suprarenal extract lays a patient open to secondary hemorrhage after the operation, and on this account he has abandoned its use. Dr. Hazlewood of New Albany, Ind., reported a fatal case of hemorrhage from the nose in which a physician previously had used persulphate of iron and a tampon, and in which he had used the suprarenal extract but without success. Dr. Thompson of Cincinnati said he believed the use of the suprarenal extract increased hemorrhage, and that he now takes the precaution to pack more carefully after its use. It gives a bloodless field at the time of operation. Dr. H. W. Loeb of St. Louis stated he did not see the utility of using the extract to prevent hemorrhage. The occurrence of a little hemorrhage tended to make one more careful. Dr. J. A. White of Richmond, Va., reported two cases which were of interest to him and of uncertain diagnosis. One was a man, forty-five years of age, who contracted whooping-cough and was apparently well of it for 2½ months when this peculiar condition developed. After attacks of coughing he would have a period of unconsciousness whether standing or sitting. The speaker was consulted because of an injury received by a fall following a spell of coughing. At the end of a coughing-spell his head would swim, and he would have a sensation of choking and a flushing of the face. His diagnosis was laryngeal vertigo. He had found nothing that did any good. In a succession of these cases what would do one good would fail in another. The other case was a fibroid growth of the tonsil in a young woman eighteen years of age. Examination of a piece removed for that purpose showed it to be a fibroma. A pedunculated or encapsulated growth can be cut down upon and removed, but this occupied the right half of the throat, extending down to the epiglottis and is a solid hard mass, without any evidences of the growth externally. He had suggested external incision for removal, but this had been denied him, and as a last resort he had used electrolysis. The lower part of the tumor had disappeared but the upper portion remained the same.

Dr. H. W. Loeb, speaking of the first case reported, believed it to be a case of true laryngeal vertigo. A case he knew of, occurring in the practice of Dr. Mulnall of St. Louis, had been much improved by a simple hygienic plan of treatment.

Dr. D. B. Kyle of Philadelphia reported the case of a man, sixty years of age, who had contracted whooping-cough from his grandchildren, who would gasp following a paroxysm until unconsciousness supervened, gradually beginning breathing again. Free purgation and the exhibition of the podophyllin and sodii phosphate gave great relief. In whooping-cough the only lesion that is discoverable is an enlargement of the glands at the back of the pharynx and esophagus, during a fit of coughing pressure is increased on the recurrent laryngal nerve.

Dr. M. F. Coomes reported the case of a woman 65 years of age in whom there was a growth similar to the one reported by Dr. White. He had

advised operative interference but when cutting down on the tumor and finding the true condition he had desisted and advised against further interference.

Dr. Kyle reported the case of a girl, seven years of age, operated upon a few days ago, who presented a peculiar condition of the mastiod. The middle turbinate was bent down and was adherent to the base of the nose. There was so little scar-tissue as to make him believe it was congenital. The tear-duct was closed and pus came from the upper opening. Under anesthesia a probe was passed through the duct, but it was not found in the nose after the removal of the turbinate. Her antrum was opened in the usual manner but no pus found nor was the end of the probe located. Recalling the fact that there might be an anomalous condition present, he made an opening from the nasal side finding a distinct cavity separated from the anterior by a septum. This was perforated to obtain free drainage.

REVIEWS.

The Modern Treatment of Wounds. By John E. Summers, Jr., M.D., Surgeon to the Clarkson Memorial Hospital. Omaha: Medical Publishing Company, 1899.

This little volume contains a good description of modern surgical principles and surgical technic, with illustrations of interesting cases occurring in the author's practice.

Operations-Vademecum. By Dr. E. Leser, Professor in the University of Halle. Illustrated. Berlin: S. Karger, 1900.

This is a very good little book filled with numerous excellent illustrations taken from larger text-books. The author has succeeded in his aim to produce a valuable and terse reference-book for the general practitioner in the country or small town.

Notes on the Modern Treatment of Fractures. By John B. Roberts, M.D., Professor of Surgery in the Philadelphia Polyclinic. New York: D. Appleton and Company, 1899.

The author has collected and revised the papers he has published on this subject in various medical journals. The book is well worth the perusal of every one interested in the subject. Complete reduction, exact restitution of contour and perfect retention are the conditions of full success, and the author gives some valuable hints for the accomplishment of this end.

Clinical Lectures on Neurasthenia. By Thomas D. Savill, M.D., Physician to the West-End Hospital for Diseases of the Nervous System; London Examiner in Clinical Medicine in the University of Glasgow, etc., etc. William Wood and Company, New York, 1899.

These lectures contain an excellent review of the present status of our knowledge with regard to neurasthenia. The lecture on the association of dyspepsia and neurasthenia is especially suggestive. Gastric derangement may very well be the basis for neurasthenia, but neurasthenia itself is very frequently a cause of the most varied symptoms of functional stomach trouble. Dr. Savill is of the opinion that the stomach symptoms in such cases have special features which enable one to distinguish them with more or less certainty from cases of true gastric derangement. The main points of differentiation are the instability and a variability of the symptoms, the fact that they bear no definite relations to meals, as in true gastric derangement, and that they are always accompanied by other manifestations of neurasthenia. Dr. Savill describes some very pronounced cases of neurasthenia from his own practice, and it is interesting to note that he considers the immediate and ultimate prognosis of the disease to be much more hopeful than some recent writers have declared.

Transactions of the British Orthopedic Society. Sessions of 1897 and 1898. Bristol: J. W. Arrowsmith, 1899.

This official document of the British Orthopedic Society constitutes the proceedings of the sessions of 1897 and 1898. Covering such an extensive period during which six sessions were held, the paucity of the subject matter considered is manifest. However, it is abreast of the advances of the hour, as shown by the discussions on coxa vera and tendoplasty. A new departure agreed to by the society was the election of corresponding members. Amongst the foreign non-residents, the leading American confrères are solely represented. This small volume of 89 pages is on the whole an improvement upon the last issue.

A Manual of the Diagnosis and Treatment of the Diseases of the Eye. By Edward Jackson, A.M., M.D., Emeritus Professor of Diseases of the Eye in the Philadelphia Polyclinic, etc. Philadelphia: W. B. Saunders, 1900.

"This book is intended," says the author in his preface, "to meet the needs of the general practitioner of medicine and the beginner in ophthalmology," and consequently we find examination, diagnosis, and treatment discussed fully and in a practical way, while rare diseases and unusual operations are but briefly referred to. A separate chapter is devoted to remedies and their applications, and another, with many cross references, deals with ocular symptoms and lesions connected with general disease. Each chapter is followed by a short bibliography of accessible recent books and papers in English suitable for supplementary reading, and there is a very complete index. The great majority of the illustrations, signed F. J., are not only new, which is rare in an ophthalmological text-book, but they are satisfactory, which is rarer.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVI. NEW YORK, SATURDAY, APRIL 28, 1900. NO. 17.

ORIGINAL ARTICLES.

SOME OF THE REASONS WHY THE SURGICAL TREATMENT OF NASAL DISEASE HAS BEEN PLACED ON A CONSERVATIVE BASIS.[1]

BY CLARENCE C. RICE, M.D.,

OF NEW YORK;

PROFESSOR OF DISEASES OF THE NOSE AND THROAT IN THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

I HAVE been asked to present to this Society a subject of such broad scope as will interest the general practitioner of medicine. I am convinced that many of the themes and discussions seen on the programs of section meetings would not be suitable here. I feel that this particular subject is in good taste because the general practitioner has done, and is continually doing much to broaden the horizon of the specialist. It need scarcely be said that the physician, who gives his sole attention to the treatment of a very limited portion of the human economy, is greatly hampered by his limitations, and sometimes forgets to take into consideration those broader etiological factors which the general practitioner places at their proper value.

It is very convenient to say here that one of the reasons why surgical operations on the nose and throat have been modified in frequency and in the severity of their character is because of a better appreciation of the fact that no one portion of the human economy can be properly considered a part by itself, independent of its intimate relation with the body as a whole; and consequently local causes of nose and throat disorder, we can safely say, are now overshadowed in importance by etiological influences proceeding from remote organs of the body.

In considering the reasons why nasal operations differ so widely in character from those which were performed in the earlier days, I have been strongly impressed by the fact that the character of the operation was formerly largely determined by the kind of instruments which happened to be devised at that particular time, and it must have been noticed that there has always been a strong inclination to employ a new particular instrument to the exclusion of all others. For example, there was a time ten years ago when many modifications of the old snaring apparatus —some of them very valuable—were added to the outfit of the rhinologist. What was more natural than to employ them? And it was not difficult to believe then that almost every case of moderate nasal obstruction, not of nasal polypi, and not even of true nasal hypertrophy, but the numerous conditions of simple vascular swelling, were suitable patients for the use of the snare. And so turbinated tissues which were performing a valuable physiological function, both in the front and in the back of the nasal chambers, were encircled by a cold wire and removed. And since this operation required considerable skill, it was a great temptation to physicians practising this specialty to perfect themselves in the use of the snare. It would be wrong to say that the snare alone was to blame for the too frequent removal of the soft tissues overlying the turbinated bones, for we know that rhinologists at that time were frequently in error in believing that these swellings were true connective tissue hypertrophies, instead of, as we now know them frequently to be, temporary vascular swellings and not the primary disorder, but due to other and more important pathologic conditions. The perfection of the galvanocautery also furnished the temptation to frequently destroy tissue when it would have been wiser to have acted in a more conservative manner. Drills and trephines, too, were used frequently, because apparently it was felt that these instruments would not have been devised unless the necessity for their use existed. Many of us remember when these instruments were invented. I recall the first electric storage apparatus—a French importation called "Trouvé's accumulator"—which was used in this country. The nasal and throat electrodes were crude in 1878 and 1879, but they were so much more attractive than any of the means of treating nasal disease which were then in the possession of the nose and throat specialist that the crudeness and unreliability of the newer instruments did not weigh much against them. It will be remembered that before this, that is, before the time of cocaine, of electrical mechanism, of spraying apparatus, and of oily medications, the physician was vainly endeavoring to astringe nasal erectile tissues with harsh solutions of silver, copper and zinc. If, with the invention of better nasal instruments, the rhinologist was tempted to use them with too little discretion it is not difficult to excuse his fault. The injudicious and unskilful use of these instruments injured for a long time the reputation of specialists in diseases of the nose and throat; not alone or so much because the leading specialists used too little discretion in their selection of cases for operation, as that semi-specialists all over the country were operating in a most careless manner. Men who had studied this specialty but a few weeks felt themselves competent to undertake any operative procedure on the nose and throat. The foremost specialists were not blameless, because they

[1] Read before the New York County Medical Society, March 26, 1900.

were the instructors of the medical public and would-be specialists, both at their clinics and in their published writings. And since they freely demonstrated at their clinics the use of snare, cautery, and drill, their example was followed throughout the country. More conservative opinions are now practised and held by the specialists in the large cities, and the beneficial result can be noted in the more reasonable application of surgical measures to nasal disease. The infatuation, also, to become specialists in any one of the many departments of medicine and surgery after a preparation of only six weeks seems to be rapidly waning. And we are reaching a period of medical study where the necessity of a thorough understanding of all that should be known pertaining to a specialty is keenly appreciated.

Another reason why operations were performed too frequently and with less preparation in this rather than in other specialties was that the nasal cavities, in their anterior part, at least, could be so much more easily reached than other mucus-lined cavities. This was proven by the fact that the specialist in the first years of his practice devoted his entire surgical work to the most anterior portion of the nostrils. We know now that usually those anterior swellings were reflex in character, but temporary congestions, and that the real source of irritation was at that time undiscovered and unknown.

We cannot in a paper of this character enter too much in detail into the pathology and etiology of the various forms of nasal disturbance which produce obstruction and disordered function, but we shall perhaps interest you when we say that a large proportion of those cases of nasal swelling which were formerly supposed to be characteristic of so-called hypertrophic rhinitis, and which were always thought to demand operation, are due to irritation arising from some other part of the nasal chambers, or are, in many instances, the exhibition of an active or passive hyperemia caused by temporary or permanent disease of organs in portions of the body quite distant. The general practitioner has aided the specialist in keeping before him the intimate relation between disturbances in the nasal circulation and cardiac, pulmonary, hepatic, and renal disorders. It is difficult for the rhinologist to determine how largely a congestive swelling in the nose is due to local causes and how much to influences remote from the respiratory tract, but it should be our constant study to determine the exact value of each of the many etiological factors. It was difficult, and before the time of cocaine almost impossible, to detect the presence of inflammatory conditions, nervous derangements, and hidden growths in the most inaccessible portions of the nasal chambers and nasal sinuses, and to trace their effect upon the easily observed swellings which were formerly supposed to be the disease itself and not, as is now known, only one of the external manifestations of the hidden trouble. For example, a nostril is examined and found to be very thoroughly occluded by swelling of all the anterior tissues, both on the turbinated and septal side; the man of limited experience needs no stronger temptation than this appearance to use snare, knife, cautery or acid. But there are many conditions behind such anterior obstruction which could easily be the cause of it, such as a foreign body, a nasal polyp, an enlarged middle turbinated bone, a septal deviation crowded against the opposite side, a catarrhal or suppurative inflammation of either the antral or ethmoidal cavities or of both, a hidden ulceration, a new growth, posterior hypertrophies, postnasal lymphoid enlargements, a local manifestation of a general hyperemia or edema, a localized exhibition of a general vasomotor derangement, not to mention numerous other abnormalities. I beg you to believe that the presence alone of swollen nasal tissue is not sufficient evidence to arrive at the true character and location of nasal disease.

The rhinologist has, we believe, arrived at the point where he is able to determine which one of many irritating factors is the most important cause of the disease, or, recognizing the presence of several disordered conditions, can give to each its proper value, and determine their relations to each other. Surgical work is now constantly performed in the nasal chambers, and when skilfully done should always result to the benefit of the patient. It is due to the rhinologist to explain one or two points which often seem to be forgotten; and one is that such forms of nasal treatment as the application of the galvanocautery and of acid to the hypertrophied tissue are not as troublesome to the patient as the old methods of treatment, when strong solutions of silver, copper, or zinc were sprayed into the nostrils. The coryzas produced by these solutions were most distressing, and very frequently produced acute inflammation of the ears, pharynx, larynx, and bronchial tubes. The destruction and removal of hypertrophies and diseased tissue when properly performed and when the wound is properly protected do not cause enough disturbance to prevent a person from pursuing his usual business.

Much of the bad reputation which formerly clung to nasal operators and operations was due to the distressing constitutional disturbances due to septic absorption which often followed surgical work in the nose. We are able now pretty thoroughly to guard against such infection, so that we do not now as formerly, see sensational reports of cases in the daily press in which a person nearly died from a supposed simple nasal operation. The reputation of nasal surgery has been greatly improved by the greater cleanliness obtained before operation through the use of some one of the formaldehyde preparations, both to disinfect the mucous surfaces and to render the instruments aseptic, and by the protection of the wound with an efficient germicide. And we must not forget to say also that now that the etiology of nasal disease is better understood, operations are less frequent and a smaller amount of tissue is sacrificed. Again, nasal surgery has lately become more conservative because it is but

recently that rhinologists have fully appreciated the intimate relation between a number of general constitutional diseases and certain pathological conditions in the nose and throat. It was found that these conditions did not yield to the most approved medical and surgical measures, and it was appreciated at length that they were manifestations of perhaps gastric, intestinal or hepatic disease or of gout, rheumatism, eczema, or some other constitutional disorder. And, further, it was satisfactorily noted that with proper constitutional treatment of these ailments the nasal swellings disappeared without surgical removal. Aside from the history of the case it is now usual to make the diagnosis of gouty and rheumatic congestion and swelling in the nose and throat by their general character and color.

We should feel that this paper furnished sufficient reason for its presentation to you, if it stated but this one proposition, namely: That there is no more powerful etiological factor in the production of nasal and pharyngeal congestion and hypertrophy and, hence, nasal obstruction than the continual overuse of alcohol and tobacco. The over-zealous specialist, in days gone by, destroyed soft and bony tissues in the nasal passages before he had insisted that his patient should diminish the daily quantity of stimulants and tobacco. But any one who has struggled to cure by local applications the actively congested pharynx of an habitual smoker and drinker appreciates how powerless his efforts have been until a reform in living has been inaugurated. If a serious attempt is made to control such congestion of the nose and throat by surgical measures, a destruction of the entire mucous lining and a consequent traumatic, dry or atrophic condition will be the result. The physician should decline to promise benefit to this class of patients unless they show willingness to cease to abuse their mucous membranes.

An important modification in the surgical treatment of nasal disease was slowly inaugurated when at length it became apparent that the wholesale destruction of the anterior turbinated tissues occasioned what may well be called "traumatic dry rhinitis." A general dryness of the mucous membrane of the upper respiratory tract naturally followed the impairment of the physiological function of the nasal tissues produced by careless operation. I am sure that all specialists have seen most annoying dry conditions of the pharynx and larynx occasioned by ill-advised destruction of nasal tissue. I have in mind as instances of this two singers who are always obliged to contend with this unfortunate dryness of their vocal organs caused by too great destruction of nasal mucous membrane. It was ascertained, too, that the real location of trouble which caused such catarrhal symptoms as hypersecretion and nasal obstruction was not so often situated in the turbinated side of the nose as in the bony or cartilaginous septum. During recent years, intelligent surgical work has been directed to the correction of septal deviations, hypertrophies and spurs.

There was a time, also, when obstructive swellings, situated at the posterior ends of the inferior and middle turbinated bodies, received far more attention than at present. It required considerable skill to transfix a posterior hypertrophy with a long needle, which was considered the necessary procedure to keep the loop of the snare in position over the swelling. This operative measure, even in the most skilful hands, was effected at the cost of a great amount of discomfort to the patient and frequently of considerable hemorrhage. Bleeding in this location was not easy to control, and the necessity of plugging the nostrils added to the general discomfort, and converted what the patient had expected to be an easily accomplished nasal operation into a very annoying one. We rarely hear now of the application of the cold snare to this locality. I think it is the opinion of most rhinologists that swellings at the posterior ends of the turbinated bodies, whether they are composed of dilated blood-vessels or of organized connective tissue, are in both instances secondary and dependent upon anterior nasal obstructions, and are disposed to rapidly disappear when the septal abnormalities have been removed. I have witnessed many times the total disappearance of what seemed to be well organized posterior hypertrophies, whitish-grey in color, and fibrous to the touch, within a week after the anterior nasal openings had been made sufficiently patent, and a proper amount of nasal respiratory pressure had been applied to these posterior growths. When, however, they are persistent, they can be reached by means of cocaine, a self-retaining palate hook, and the application of some one of the chemical caustics, and reduction can be accomplished without bleeding and with little discomfort.

It is easy to recall the days before such a disease as suppurative ethmoiditis was known, and when such a characteristic symptom as a unilateral discharge of pus was hardly sufficient to impress on the mind of the observer the fact that such a nasal discharge could not be evidence of a simple nasal catarrh. Redness and swelling were present and these were deemed sufficient to establish the existence of a catarrhal process. Again, unwisely, agents were employed to destroy tissues which were congested because of the deep-seated ethmoidal trouble and because of the pus, which, coming from the ethmoidal cells, irritated everything with which it came in contact. We may say, also, that frequently the same surgical mistake was made in the treatment of suppurative inflammation of the other sinuses. To-day the diagnosis of sinus disease is accurately made, and the surgical measures for treatment intelligently applied.

Only a word in regard to that large class of disorders which are placed under the heading of either atrophic or dry rhinitis. There it but little opportunity for the destruction of nasal tissue here, no matter how anxious the physician may be to operate, but in the old days some excuse

for either burning an atrophic surface with the electric cautery or removing a portion or the whole of the middle turbinated bone with the cold snare seemed frequently to have been at hand. To-day conservative surgery only permits the removal of as much of the middle turbinated as is necessary to prevent its contact with the septum and to secure proper nasal drainage.

We cannot close this paper without referring to the very greatly improved methods of removing post-nasal adenoids. This condition does not exist at present more frequently than formerly, but its presence is now readily discovered. Children formerly having these enlargements in the nasopharynx which completely blocked the posterior nasal orifices were supposed to be affected with nasal catarrh. Instead of destroying nasal tissue, the post-nasal space is now cleared of all obstruction.

It would require too much of your time, even if it were desirable, to briefly describe the surgical methods which are now applied to the many interesting pathologic nasal conditions. We can only say that the results of surgical treatment in the field of rhinology are vast more satisfactory than they were ten years ago. Earnest workers in the pathology of this department of medical science have simplified the clinical phenomena of many nasal disorders which but a short time ago were not understood, and this increased knowledge, together with a clearer understanding of the etiology of nasal affections, has furnished to the operator great incentive for a most desirable conservatism.

STATISTICS OF ONE HUNDRED CASES OF CANCER OF THE BREAST AND THE RESULTS OF OPERATION.[1]

By CLARENCE A. McWILLIAMS, M.D.,
OF NEW YORK.

The frequency of this disease warrants most careful attention and study, and the early recognition and diagnosis of the condition present are all the more important in the light of the fact that eighty per cent. (according to Billroth, eighty-five per cent.) of all neoplasms of the breast are carcinomatous, and that a cure can be hoped for only when the operation is performed in its incipiency. In the following table an attempt has been made to collect the principal points in the histories of the cases of cancer of the breast occurring in the Presbyterian Hospital, New York, from January, 1889, to April, 1899. One hundred cases have thus been tabulated, and the following points elicited:

Etiology.—Marriage, child-bearing, nursing or not, and disorders of menstruation have not been proved to have exerted a causative influence. The disease occurs in all social conditions, and persons in perfect health are attacked as often, if not oftener, than those in poor health. In our statistics only two cases had any hereditary taint. None of our cases developed in pregnancy or lactation, and it is an old saying that a tumor which makes its appearance during either of these periods is almost certainly not cancer. An antecedent suppurative mastitis was present in only three cases.

Trauma.—The significance of an antecedent trauma is still under considerable dispute. The situation of the breasts renders them exposed to various forms of injuries, and almost every woman when asked is able to think of numerous times when she has received injuries of greater or less degree to one or both breasts. In our list there is a record on this point in 65 of the patients, of which number 29, or 44.6 per cent., gave the history of a distinct antecedent trauma.

Marriage has been said by some to have a direct influence upon primary cancer of the breast, as high as eighty per cent. being given as occurring among married women. Seventy-four of the patients were married, or 74 per cent.

Childbirth.—Forty-eight patients present facts bearing upon this point. Of this number 32, or 66.6 per cent., had borne children, the average number of children to each patient being five. Accurate details as to nursing can unfortunately not be given, as the histories are very deficient on this point.

Symptoms.—Unfortunately, for the good of womankind, there are no subjective symptoms in the incipiency of cancer of the breast, and the first symptom, in the vast majority of the cases, is the accidental discovery of a hard, not sensitive, painless tumor in the breast, and the absence of pain disarms the patient's suspicions as to its malignancy; consequently, the family physician is not consulted. Pain, as a rule, is not at all pronounced till the surface of the tumor has ulcerated, or till enlargement of the axillary glands has occurred, which press upon the branches of the brachial plexus and cause neuralgic pains down the arm. There may be, however, while the tumor is yet small, a sense of discomfort in the breast, amounting at times, particularly during the menses, to a dull ache. Out of 96 cases, 54, or 56.2 per cent., had some local discomfort or ache prior to operation. It is a remarkable fact that cancers of the breast may attain a large size without the slightest twinge of pain. This may be accounted for by the fact that the advancing, invading cancerous tissue paralyzes the nerve-filaments with which it comes in contact. In respect to pain cancer is somewhat distinguished from benign tumors of the breast, the most frequent of which results from chronic mastitis, which is prone to be a painful process.

Retracted nipple depends on the position of the growth, which will not affect the nipple if it be situated on the periphery of the gland. Retraction of the nipple is caused by the pulling in toward the growth of all the tissues in its neighborhood. Of 73 of the cases about which there is information in this regard, 33, or 45.2 per cent., had retraction of the nipple.

Situation.—In 51 of the cases the right breast

[1] Prepared for the Medical and Surgical Report of the Presbyterian Hospital, Vol. IV.

was involved, and in 49 the left. Right breast, the inner quadrant was involved in 21 cases; outer quadrant in 9 cases; left breast, inner quadrant in 10 cases; outer quadrant in 19 cases. In the remainder of the cases the tumor was near the center of the gland. In no case were both breasts primarily involved at once.

Axillary Lymphatic Gland Enlargement.—Out of 98 cases, 48, or 48.9 per cent., had the lymphatic glands in the axilla palpably enlarged. It is imperative in all cases of mammary cancer to remove all the lymph-glands in the axilla, even although they may not be palpably enlarged when the axilla is opened; for even in this case microscopical examination often reveals a cancerous invasion of the glands. This is clearly shown in our table, in which the axillary glands of 75 cases, after their removal, were examined microscopically. Out of this number the axillary glands in fifty-nine of the cases, or 78.6 per cent., showed distinct cancerous infection. In Case 13 the axillary glands were both cancerous and tuberculous. There seems to be no rule as to how long a time elapses after the tumor has appeared in the breast before the glands become involved. In some cases it is apparently a simultaneous process, while in others a considerable time passes before changes in the axillary glands are appreciated. Hence, the absolute necessity for as early an operation as possible after the appearance of the tumor. Naturally, the question of prognosis depends largely on whether the axillary glands are invaded or not. Should we not go still farther in our operation and remove the supraclavicular glands? Halsted of Baltimore urgently insists upon this. He excises both the axillary and supraclavicular glands in all his cases, and says the additional time occupied in removing these glands adds nothing to the mortality of the operation. He has cleaned out the supraclavicular fossa in 67 cases and cancer was found in the tissues removed 23 times, or in 34.3 per cent.

Cachexia.—This was not a very prominent symptom in our cases and is not apt to develop early. Fourteen cases only showed any cachexia, and these to only so slight a degree as not to contraindicate operation.

Age.—The average age was forty-nine years, six months, and twenty-six days, distributed as follows:

Between	25	and	30	years....	1	case.
"	30	"	35	"	9	cases.
"	35	"	40	years....	9	"
"	40	"	45	"	18	"
"	45	"	50	"	12	"
"	50	"	55	"	10	"
"	55	"	60	"	16	"
"	60	"	65	"	15	"
"	65	"	70	"	5	"
"	70	"	75	"	3	"

The youngest patient was Case 38, who was twenty-nine years of age; and the oldest was Case 1, who was seventy-two years of age.

Operation.—The incisions were made so as not only to remove the infected skin overlying the tumor, but to get so far into healthy skin as to endeavor to avoid any possibility of cancerous infection. The necessity for this is evident when we consider that recurrence most often takes place in the skin around the scar or in the scar itself, and in observing these cases I am led to believe that not enough skin has been habitually removed. The desire to approximate the skin edges should not be allowed to interfere with the liberal excision of skin, as this is of very minor importance when compared to the necessity for a total extirpation of the growth. The dissection is then begun in the axilla and the incision carried down to the pectoralis major tendon, under which, when exposed, the finger is passed and the tendon divided near its insertion upon the finger. The axilla is then laid open by dividing the fascia beneath the great pectoral, and the axillary vein is clearly identified, the situation of which should never be lost sight of as it is the guide to the whole space. The pectoralis minor muscle is now exposed and its tendon divided and reflected back toward the chest with the entire mass. The removal of the pectoralis minor gives much easier access to the very apex of the axilla, and hence greater certainty of removing infected glands, and as the removal of this muscle makes practically no difference in the function of the arm afterward, it should always be removed. The axillary contents, consisting of fat and glands, are dissected back from the apex of the axilla toward the breast. This is a better method of procedure than to proceed from breast to axilla in the dissection, in which case we are more likely to press into the general lymphatic system cancerous cells. The breast, muscles, and axillary contents should all be removed in one piece, since cancerous tissues should never be cut into, nor across, nor removed piecemeal for fear of spreading infection. The subscapular nerves are preserved, if possible, although, if embedded in a mass of enlarged glands, they are removed. The whole mass is then cut away from the chest. This operation seems to be a mutilating one, but the after-results are surprising. One would expect considerable disability after the removal of so much muscle, but such is not the case. The patients may complain for a few months of stiffness and weakness in the arm, but the arm regains its former strength. The functions are maintained by the anterior fibers of the deltoid and the clavicular portion of the pectoralis major. Should the axillary vein be found embedded in a mass of enlarged glands, a portion of it is divided between ligatures. In this case more or less permanent edema of the arm may be expected. A drainage-tube is generally left in the bottom of the wound for thirty-six or forty-eight hours, as there is usually some oozing. The edges of the wound are brought together as closely as possible by sutures throughout the extent of the wound. This is often facilitated by separating the inner skin edge from the chest for two inches back, which

allows this edge to be drawn farther externally. Any defect between the skin edges is allowed to granulate, or if considerable is grafted at the time of the original operation or afterward. Halsted removes so much skin that he is never practically able to approximate the skin edges; to remedy which he always grafts skin at the time of the original operation. After copious dressing has been applied, the arm is bound to the side by a roller bandage, the forearm and hand being allowed to remain free, which adds much to the comfort of the patient.

Mortality.—It is one of the remarkable facts in surgery that an operation of such apparent magnitude, which is attended by some loss of blood, and which is at times a prolonged one, should be accompanied by such a low death-rate; the few nerves which are cut possibly account for the small amount of shock. In the following 100 cases, 4 deaths, or 4 per cent., only can be directly traced to the effects of the operation. One patient, Case 85, died three days after operation of suppression of urine; two others, Cases 6 and 22, developed post-operative pneumonia, while Case 18 died four hours after operation from shock. Of the 4 other cases which died in the hospital, the fatal result can in no sense be attributed to the operation. Case 61 died at the end of three weeks from presumably secondary cancerous deposits in the mediastinum and lungs, but this occurred a week or more after the patient had been out of bed. Case 60 died on the thirty-first day of nephritis and some secondary cerebral lesion. Case 63, one of the oldest of the series, died at the end of two months of senile changes. Case 30 died of secondary cancer of brain. This gives an operative mortality of 4 per cent.

Death from sepsis has not occurred. The low mortality-rate leads us to undertake the operation even in cases where we cannot hope to thoroughly eradicate the disease, for the operation will ameliorate the patient's condition and will prolong life. No death is more trying for the patient, and the patent's friends than that caused by an ulcerated, sloughing cancer of the breast, and metastasis of an internal organ is infinitely to be preferred as a cause of death. Mortality statistics of others are: Bull, 3.6 per cent.; Curtis, 6 per cent.; Weir and Dennis, no deaths in a reported series of 125 and 33 cases respectively.

The average length of stay of each patient in the hospital was twenty days. The patients are encouraged to sit up in bed as soon as possible after the operation, generally about the fourth day, and to get out of bed about the seventh day, sometimes even as early as the fifth day. Convalescence is consequently very rapid. Movement is allowed at elbow on the second day after operation and from the shoulder after the tenth day; massage at the end of a week is given to the muscles of arm and shoulder.

Recurrence.—We now come to the most interesting part of our report, and we shall endeavor to ascertain how much good has been done these patients, and what can be said as to prognosis after operation. To accomplish this an endeavor has been made to get news of each patient in the list; to see personally the ones who are alive, and to get accurate information, when possible, from the physician in attendance, regarding the cause of death in the fatal cases. Of the 92 patients who went out of the hospital, statistics have thus been obtained of 66. No trace has been found of 26, the reason for which can easily be appreciated when we consider the difficulties in the way of tracing patients belonging to the class which we find in the average hospital ward. These statistics were all obtained on or about December 1, 1899.

Number of Cases free from Recurrence at Yearly Periods from Operation:

			Per cent.
At end of 1 year	36 cases out of 61,	or	59.1
" " 2 years	19 " "	"	52, " 36.6
" " 3 "	17 " "	"	50, " 34.0
" " 4 "	13 " "	"	46, " 28.2
" " 5 "	9 " "	"	43, " 20.9
" " 9 "	3 " "	"	37, " 8.1
" " 10 "	1 " "	"	35, " 2.8

If we adopt three years of immunity from recurrence as the limit of time when we can say a patient is cured, 17, or 34 per cent., of the patients were cured.

Halsted of Baltimore published, in 1898, his statistics on cancer of the breast, giving 41 per cent. of cures after three years. Other results of cures after three years are as follows, all published in 1894:

	Per cent.
Bergmann	30.2
Billroth	4.7
Gusselbauer	16.7
König	22.5
Volkmann	14.0
Bull	26.6
Curtis	20.7
Weir	20.0
Dennis	25.0

Table of Recurrence.

Recurrence has taken place within 3 months in 4 cases.

Between	3	and	6	months	in	7	cases.
"	6	"	9	"	"	3	"
"	9	"	12	"	"	7	"
"	12	"	18	"	"	6	"
At 1 year		"	10	"	"	1	case.
" 2 years		"	6	"	"	1	"
" 4 "		"	2	"	"	1	"

Four patients died of recurrent cancer, in whom the time of recurrence was not ascertainable:

One at 2 years	Case 73
" 2 months	Case 68
" 3 "	Case 26
" 6 "	Case 42

It is, therefore, clear from these tables that all the recurrences took place within two years of the operation, except in two patients, one of whom (Case 67) died four years and three months after operation of cancer of the lung. Shall we call this a recurrence after four years, or is it not truly a case of re-infection, in which the original disease had no influence? The second patient (Case 53) died two years and six months after operation from cancer of the brain. Twenty-one cases recurred in the first year, and twenty-eight within two years. There are some interesting statistics concerning the location of the recurrences:

Recurrence.

Local,	in scar or skin about scar,	in 15	cases.
"	" lung	" 6	"
"	" opposite breast	" 3	"
"	" liver	" 2	"
"	" brain	" 2	"
"	" supraclavicular glands	" 2	"
"	" stomach	" 1	case.
"	" pleura	" 1	"
"	locality unknown	" 2	cases.

The clinical history subsequent to operation of several of the cases is interesting.

Case 17 had a small tumor of breast, of five months' duration, removed July 1, 1897, by Dr. McCosh, which, after careful pathological examination, was found to be chronic inflammation. Eleven months afterward another tumor appeared in the same breast, and this time a radical operation was performed, the breast, pectoralis major, and axillary contents being removed. Pathological examination of the breast tumor revealed "Chronic inflammation, with much proliferation of cells," while the axillary glands showed carcinomatous infection. Twelve months later, metastasis took place in liver. The patient is still alive, but very ill. How are we to explain this case? How much influence had the chronic mammary inflammation to do with the axillary cancer?

Case 37 had one breast removed by a radical operation for cancer, June 23, 1897. Without any local recurrence, a tumor appeared in the opposite breast April 1, 1898. Radical operation was performed in April, 1898, and the tumor and axillary glands pronounced to be cancerous. No recurrence was discoverable December 1, 1899, two years and five months after the first operation, and one year and eight months after the second. The patient has perfect use of both arms and works for her living.

Case 53 was exceedingly interesting. For notes on this case I am indebted to Dr. Stillwell. The breast was removed radically June 23, 1896. The patient was well for two years and six months, when, in December, 1898, she began to complain of difficulty in expressing herself, and of dulness of mind. Three months later, March 9, 1899, she developed some loss of muscular power in the right arm, difficulty in concentrating the mind, and slowness of speech. Was also emotional. Had no headaches. March 17th, right arm showed marked loss of muscular power. Pulse absolutely normal; also kidneys and lungs. Sensation normal in right arm. Cerebration was sluggish; did not confuse words. No headache, no vomiting. March 28th had a severe chill, and during day had three fainting attacks, in which pupils were contracted but equal, was semi-conscious, and total paralysis of right arm and leg developed. March 29th, after use of powerful cathartics, intelligence cleared up, paralysis became much better, *i. e.*, had slight movements in arm and leg (alleviation of symptoms possibly being due to the relief of cerebral edema), March 30th, greatly improved, pupils normal, could read intelligently, and talked well. April 2d, pulse was 68, no fever. Mind sluggish and drowsy. Speaks correctly when questioned, but in monosyllables. April 3d, slight dysphagia developed, moves leg fairly well, but arm not at all. Seems weaker, no vomiting, no headache. April 4th, mentally clear. Can move arm slightly. April 5th, moves arm slightly, clear mentally up to end, no vomiting nor headache at any time. Pulse, 120, action weak and heart bad; breathing became labored, and she died suddenly April 5th. Autopsy showed that the two vertebral arteries were not obliterated, only slight general atheroma. Left anterior and middle lobe centrally softened, so that section was impossible; and under the convolutions and in center of this soft mass, was a hard, sharply defined mass, the size of a small egg. Microscopical examination showed this to be medullary cancer.

Case 38 died eighteen months after operation of metastatic cancer of the brain. She was well for nine months, when she began to complain of headaches which were intractable. Four months later the headaches became agonizing, particularly at night, and rendered sleep impossible. Left-sided facial paralysis developed two months before death, and paralysis of speech two weeks before death.

Death has taken place in the recurrent cases on an average one year, two months and twenty days after the operation. The average length of time after recurrence set in till death took place has been five months.

In concluding the subject of recurrence and considering the facts before us, we are, unfortunately, obliged to confess that we can never promise to absolutely cure a patient with cancer of the breast by operation. If the case is seen while the tumor is yet small and there is no axillary gland involvement, we can tell the patient's friends that a cure is very possible, but not by any means certain. We know we can cure a certain number; but our knowledge is not as yet deep enough to select from a given number of cases those which will not have a recurrence, and those which will recur. Thirty-four per cent. of these cases, we have seen, were cured (*i. e.*, passed the three-year limit without recurrence). This percentage is not absolute, however, because not all the patients operated on over three

years ago could be found, consequently we know not whether this percentage would be increased or diminished had we been able to trace them all. The fact remains, however, that at the end of three years, 17 patients were perfectly well, which is a very excellent showing compared with earlier results, and well calculated to convince any who may think the operation of doubtful utility. With recurrence taking place in the scar or its neighborhood in 15 of the cases, it would seem that it has not been the custom to remove enough skin with the breast. Have we sufficient warrant to subject the patients to the additional ordeal of removing the supraclavicular glands, in view of the fact that in only two cases was recurrence primarily in these glands? If the process has gone on so far as to infect these glands, is not a general infection very probable, and will their extirpation be more likely to effect a cure?

These considerations are worthy of careful attention. The tendency is to extend the operation. Where shall the line be drawn?

In conclusion, I venture to assert that many of the profession feel that this is an operation which is merely palliative. These statistics prove that such a feeling is a false one, and calculated to do immense harm. It is the duty of the profession to impress upon the laity the idea that the smallest nodule in the breast may become a source of the greatest danger to life, and that the only hope of a cure lies in early and radical operation. A summary of the points elicited in the preceding article, as well as a table of the cases follows:

Summary.

Trauma present in 44.6 per cent. of the cases.
Married, 74 per cent. of the cases.
Children born to 66.6 per cent. of the cases.
Average number of children to each, 5.
Pain present in 56.2 per cent. of the cases.
Nipple retracted in 45.2 per cent. of the cases.
Right breast involved in 51 cases.
Left breast involved in 49 cases.
Axillary glands palpable in 48.9 per cent. of the cases.
Axillary glands found cancerous by microscope, 78.6 per cent of the cases.
Average age was 49 years, 6 months, 26 days.
Mortality of operation was 4 per cent.
Average length of time in hospital, 20 days.
Prolongation of life for one year, 59 per cent.
Prolongation of life for two years, 36 per cent.
Cured (no recurrence at end of three years), 34 per cent.
Recurrence took place in one year in 21 cases.
Recurrence took place in two years in 28 cases.
Recurrence took place locally in 15 cases.
Recurrence took place in lung in 6 cases.
Average length of time in recurrent cases from operation to death, 1 year, 2 months, 20 days.
Average length of time from period of recurrence to death, 5 months.

53 West Fifty-Second Street.

CANCER OCCURRING IN ACID PARTS OF THE BODY.

BY A. L. BENEDICT, M.D.,
OF BUFFALO;
PROFESSOR OF PHYSIOLOGY AND DIGESTIVE DISEASES IN THE DENTAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO.

THE relative frequency of primary cancer occurring in the stomach as compared with cancer of the bowel, and of cancer of certain small portions of the bowel as compared with the greatest part of the small intestine, must often have appealed to the student of digestive diseases as possessing a hidden significance. The recent suggestion—it can as yet scarcely be given a more positive term—that cancer is due to a micro-organism analogous to, if not identical with, the yeasts, has led the writer to undertake an investigation of statistics to learn if the reaction of different parts of the body has any determining influence on the location of cancer. All the juices of the body are ordinarily alkaline in reaction, excepting four, *viz.*, the perspiration, urine, gastric juice and cervicovaginal mucus. It may be said in anticipation that whether the essential cause of cancer be a yeast, some other kind of germ, or merely an excited epithelial vitality, statistics show that the great majority of cancers develop in acid media. Whether the reaction is the determining factor, whether, as is certainly often the case, acid parts of the body happen to be parts in which mechanical traumatisms are frequent, or whether the localization is due to some unsuggested cause, the writer does not pretend to state. In fact, he prefers not to be considered an advocate of any theory, so long as the etiology of cancer remains obscure. It is, of course, understood that this paper deals with primary cancers, and that nothing is suggested to confirm or reject the commonly accepted ideas as to metastasis.

Especially with reference to the digestive tract, it is important to bear in mind certain facts. While all the secretions of the alimentary canal and its tributary glands (the salivary glands, liver and pancreas) are alkaline in reaction, except that of the intramural gastric glands, organic fermentation plays a very important part in determining acid reaction in certain places. Food particles in the mouth, especially along the dental margins and in the tonsillar crypts, are prone to ferment, producing various organic acids to which was, indeed, ascribed the production of dental caries until the development of bacteriology as a fairly exact science within the last fifteen or twenty years. The corners of the mouth, the gums, the portions of the tongue not readily cleansed by its own movements and especially the parts near the circumvallate papillæ, the tonsils, are preëminently the parts selected by cancer. The esophagus is subject to little interference from without, except at meal-times, and is bathed in a tenacious, alkaline mucus for more than nine-tenths of the time, except at its inferior extremity, where it is exposed to acid regurgitation from the stomach for quite a time

after each meal. It is at this point that most esophageal cancers are located. (Pepper's System, or, in fact, any authority.) The duodenum is, for several hours after each meal, subject to periodic waves of acid chyme. The small intestine below the entry of the pancreatic and hepatic secretions is uniformly alkaline, except for fermentation in the central mass of chyle. There is free secretion, exceeding the amount lost by absorption under ordinary conditions; the absorption is by means of projecting villi and all absorbable products are fresh from the activity of alkaline secretions. Thus, the mucous membrane is protected by an abundant current of alkaline secretion from whatever irritating acid masses may be present in the lumen of the bowel. In the large intestine, or even a little before the ileocecal valve is reached, the conditions change. Bacterial fermentation becomes more marked, the amount of secretion from the intestinal wall is absolutely less than in the small intestine and the current is one of absorption toward the mucous membrane, which must, therefore, often be subjected to an acid irritation.

Cancer statistics are by no means satisfactory. For instance, the first question that naturally presents itself is as to the classification and enumeration of cancers according to the blastodermic layer from which they are produced. It is, of course, obvious that, except for an inclusion of stray cells in development and that the cells of organs derived directly from the so-called genito-urinary cell-mass always retain a vestige of power to develop into any kind of tissue, cancer can occur primarily only in epiblastic and hypoblastic epithelium. Yet there are no statistics of any magnitude bearing on this question, and it is not even easy to obtain positive general statements regarding the blastodermic origin of different cancers, or an explanation of the characteristics of cancers of different organs, with their cellular genealogy in view.

Tyson states that barely five per cent. of all intestinal cancers occur in the small intestine, yet this part of the bowel has eighty per cent. of the total length and probably 70 per cent. of the total epithelium. Fifteen per cent. occur in the cecum and colon. All detailed reports of small series agree that the great majority of this group are located within a few inches of the ileocecal valve. Eighty per cent. occur in the rectum, which comprises not more than three per cent. of the entire bowel. This part of the intestinal tract is not subjected to the constant presence of contents and bears the brunt of the chemical irritation only at times.

Maydl collected at the Vienna Pathologic Institute 41,838 necropsy reports, including 3,583 of cancer. Only 343 of these affected the intestine, although the majority of the total hypoblastic epithelium is found in its wall. Of the 343 intestinal cancers, 162 occurred in the rectum, 164 in the colon, which is more than four times as long, and 7 in the duodenum. Not one is charged to the jejunum and only 10 to the ileum. Although their exact location is not given, it is safe to assume that most of them, as in similar series, were well down toward the ileocecal valve. In fact, Alois Pick, alluding to these very statistics, although not in detail, makes this statement. Thus, of the 343 intestinal cancers, only a minority of the last ten occurred in distinctively alkaline parts of the bowel, although the latter comprise a length of about twenty feet, as contrasted with about two feet of the points of election for the majority of cancers.

Primary cancer of the spleen (inclusion growths), pancreas, gall-bladder and liver, is comparatively rare, although all except the spleen represent considerable aggregations of hypoblastic epithelium. Fully three-fourths of all cases of hepatic cancer, according to Tyson, are secondary to growths in the stomach, and Welch is in practical agreement, putting the fraction at two-thirds. Musser, from a study of 100 cases of cancer of the biliary ducts and bladder, says that primary growths are rare and usually due to previous irritation by gall-stones. These, in addition to their mechanical irritation, are now known to be connected with bacterial invasion, especially of the colon bacillus, which produces hydrosulphuric acid from nitrogenous pabulum.

If we consult any large series of cancer cases, barring some with peculiar standards of selection, we find that the plurality of cancers is possessed either by the stomach or the uterus, both acid organs and of relatively small size. Welch's average of 31,482 cases from various European and American sources was 21.4 per cent. for the stomach, 29.5 per cent. for the uterus. The latter really represents about double the apparent tendency, being limited to females. It is only fair, however, to consider the fact that cancer is rare in nulliparæ and that traumatism must have an important bearing. Still, it is a question whether the traumatism is a direct cause or whether laceration of the cervix acts by exposing the cervical epithelium to chemical irritation from the vagina.

In considering any series of statistics regarding epithelioma alone, the acid theory receives confirmation which is largely specious, since squamous epithelium occurs to a slight extent inside of the skin. This is bathed in acid perspiration and to a greater or less degree, in fermenting sebaceous matter. Satterthwaite's series of 94 cases of epithelioma ("Reference Hand-Book of the Medical Sciences") assigns twenty-five per cent. to the lip, six per cent. to the tongue, three per cent. to the larynx, two per cent. each to the mouth and palate. Löwenthal published in 1895 a series of 800 cases of apparently traumatic tumors, including 358 cancers of which 152 occurred in the breast, where special reasons for such growths occur. I may digress to state the belief that the history of gross traumatism of the breast has been given undue prominence. Aside from physiologic stimuli, occurring not merely with lactation but with every menstruation, the breast is frequently the seat of mild traumatisms,

not only from nursing but in caresses and by the pressure of the corset, etc. Just half of the remaining 206 cancers occurred in the face, but the avowed purpose of the collection, the tabulation of traumatic growths, would inevitably include a disproportionate number of face cancers. In this connection, it may be remarked that few cancers appear to be due to shaving. Men show no marked predisposition to facial epithelioma. It occurs about as often in those men who wear beards as in those who shave, and it usually occurs above the line of the beard. But it would be too far-fetched to explain this on the ground of a liberal application of alkaline lather to the area of shaving. Löwenthal's other figures are as follows: Jaw, 16 per cent.; neck, 1 per cent.; back, 2 per cent.; abdomen, 8 per cent.; upper extremities, 18 per cent.; lower extremities, 26 per cent.; urinary organs, 17 per cent.; pelvis and lumbar region, 0 per cent. Thus, the limbs are more liable to cancer than the trunk. In proportion to their size, there is no significant difference between the arms and legs. The urinary organs certainly show a proportionately great liability, perhaps due to the fermentation of urine, smegma, etc., and to relatively free perspiration. The axillæ and umbilicus, although subject to free perspiration and fermentation of sebaceous matter, are quite free from cancer.

Of 180 scirrhous cancers collected by Satterthwaite, 130 involved the breast, including the nipple. The fact that cancers, as well as pyogenic affections of the breast, often begin at the nipple may be taken to show a predisposition on account of acid fermentation, which is certainly frequent at this point. But we must not overlook the fact that the mammary glands, although epiblastic, resemble, both histologically and in the character of their neoplasms, hypoblastic structures, and that no other epiblastic tissues are fairly comparable with them. Of 50 other cases of scirrhus, 35 occurred in acid parts; stomach 18 (with metastasis to the liver in 4), uterus 8, rectum 4, bladder 2, colon, duodenum and ileocecal valve, 1 each; while distinctly alkaline parts were affected in only three cases; pancreas 2, gall-bladder 1; and twelve cases occurred in parts of doubtful reaction: or the location of the tumor is not given exactly enough to warrant a definite conclusion; neck 4, axillary glands, back, foot, nose and parotid region, superior maxilla, cheek, esophagus, each 1. If we assume that the cancer of all of the skin-covered regions of this list of 12, began in the skin epithelium, 10 more can be claimed as occurring in acid parts.

Satterthwaite's series include only 10 cases of medullary carcinoma and this series neither supports nor opposes the acid theory, unless we assume that important glands like the liver and spleen are in a state of acidity during functionating periods—for which there is good physiologic authority as regards the spleen, at least. If, in addition, we assume that the mammary cancers originated at the nipple, every one of this series of 10 may be assigned to acid parts. Only 2, however, occurred in parts having a practically permanent acidity, the kidney and vagina.

The United States census of 1890 reports 18,536 deaths from cancer, a little more than two per cent. of the total death-rate. Of these, 5793 are unspecified in location or are referred in a general way to the abdomen. Of the 12,743 specified cancers the location was as follows: Stomach, 4307; uterus, 3510; bladder, 124; genitals, 57; rectum, 414; head, face and neck, 1206; extremities, 169; making a total of 8787 occurring in distinctly acid parts. Breast, 1714; liver, 1293; mouth, tongue and throat, 642; a total of 3649 which occurred in parts of doubtful reaction. Brain, 51; eye, 72; larynx, 46; lungs, 79; ovaries, 49; testes, 10; a total of 307 which occurred in alkaline parts.

Cancers of the pancreas and small intestine were lumped together in an item of only 923 abdominal cancers, obviously including the kidneys and extensive growths from the stomach as well as the lower bowel. It is also incredible that 10 per cent. of all cancers originated in the liver. Fully 6 per cent. of these should be charged to the stomach, according to Welch's opinion. But without any of these allowances, it is significant that about 70 per cent. of all cancers occurred in distinctly acid parts, only about 3 per cent. occurring in distinctly alkaline parts.

William's statistics, based on reports of English hospitals and limited to primary neoplasms, are as follows:

For males, total 4597, 15.9 per cent. being unspecified or undetermined. In acid parts there were: Tongue and mouth, 15.9; skin, 16.4; external genitals, 6.1; rectum, 5; stomach, 4.8, and prostate, .2, making a total of 48.4. Those of doubtful origin were: Lips, 7.3; maxillæ, 3.9; mammæ, .5, and esophagus, 3.1, making a total of 14.8. Those occurring in alkaline localities were: Connective tissue, 9.4; other bones, 6.1; brain, 3.4, and testes, 2, making a total of 20.9.

For females, total 9227, 5.8 per cent. being unspecified or undetermined. In acid parts there were: Uterus, 28.7; skin, 5.9; external genitals, 4.6; rectum, 2.5; tongue and mouth, 1.6, and stomach, 1.4, making a total of 44.7. Those of doubtful origin were: Mammæ, 26, and maxillæ, 2.4, making a total of 28.4. While those occurring in alkaline localities were: Ovaries, 8.7; connective tissue, 6.9; bones (except maxillæ), 2.9; brain, 1.4, and liver, 1.2, making a total of 21.1.

The discrepancy between these and the preceding statistics is easily accounted for by the nature of the series. Williams deals with surgical cases and his statistics were published before operations for radical cure of neoplasms of the stomach, liver, etc., were at all frequent. Thus, instead of tabulating 25 or 30 per cent. of gastric cancers and 2 or 3 per cent. of (primary) liver cancers, he notes a low percentage of each. The fact that he was a general surgeon rather than a gynecologist is shown by the fact that he saw only 28.7 per cent. of uterine cancers among wom-

en, whereas such cancers amount to as high a percentage of the total population, *i. e.*, to about double Williams's percentage of cancers for women. In fact, what Williams takes as 100 per cent. really represents only about 70 or 80 per cent. of the total cancerous population, or rather of an average representation of it.

It is proper to call attention to the relations of this theory to other more or less accepted views as to etiology. To the microbic theory of cancer, whatever be the exact nature of the germ, the acid theory applies merely with regard to the localization of the growth, and it is certainly in harmony with our knowledge of other infections, notably tuberculosis and diphtheria, to suppose that special characteristics of a tissue influence the development of the disease. The dry, squamous epithelium of the skin shows comparatively little predilection for cancer, nor does one area seem notably more prone to cancer than another of the same size. While the marked liability of the genitals and other muco-cutaneous areas as compared with other parts of the skin might support an argument for the acid theory, it is only fair to suppose that the softness of the epithelium has more to do with this tendency. If we contrast the bladder and rectum, on the one hand, with the mouth, nose and throat, on the other, we have nearly equal areas of infolded epiblast, the latter much more subject to traumatisms, but each group subject to cancer in nearly equal degree. In referring to the stomach as an acid cavity, the idea is based not so much on its normal secretion of HCl as on the liability to organic fermentation. In conclusion, the writer wishes again to emphasize the fact that he is not a partisan of a theory, but that these statistics are presented as a basis for further study.

AFTER-TREATMENT OF TENOTOMY.[1]

By ALEXANDER DUANE, M.D.,
of New York.

After a tenotomy, whether performed for a squint or heterophoria, there are two plans of treatment open to us. We may either bandage the eye operated on and discourage any attempts at using the eyes, at least for binocular vision, until the wound is healed; or we may leave the eye open immediately after the operation and encourage the patient to begin using his eyes at once for all ordinary vision. In the first method we aim to fix the eye in the position left by the operation, except so far as we modify that position by another operation, *e. g.*, by the insertion of sutures, etc.; in the second method we attempt, by utilizing the directive force of the eyes themselves and, if necessary, by suitable exercises, to gradually substitute a more accurate correction for the approximate one produced by the tenotomy.

The *principle* underlying this second plan of treatment, to which I in common with others give the preference, is as follows: If there still remains any tendency to binocular vision, the eyes, even although deviated, will constantly strive to assume their proper relations to each other, so far as they can. Under ordinary circumstances, this effort is nullified, indeed sometimes reversed, by the conditions acting to maintain the deviation. But in the days immediately succeeding a tenotomy, when the tissues are still plastic and the severed tendon still able to shift somewhat its point of attachment to sclera, this tendency to spontaneous restitution is able to assert itself and acts gradually, but automatically, to set the eyes straighter than we left them by our operation. It is our part to give this tendency full play. Accordingly, after detaching the tendon from its insertion and putting it as nearly as we can in the place desired, we allow this automatic action of the eyes at once to begin working, so that it may act to the best advantage and gradually put and keep the tendon in just the proper position. In this way we convert an approximate result into a more precise one; just as the microscopist supplements his coarse adjustment that brings the object incompletely into view by a series of fine adjustments which focus it sharply.

Being thus left open and free to move, the eyes are *practised from the moment of operation in looking*, especially in steady looking at remote objects. Care should be taken that at first they are used mainly for distant vision—certainly for no very fine or continuous near work—and that the patient avoids all sudden, jerky movements of the eyes or head as well as any stooping and straining. Measurements of the amount of heterophoria are made every day, and from these measurements deductions are drawn as to the amount and kind of eye-work that the patient may be permitted to do.

Obviously, the eyes should be placed in the very best conditions for seeing, and all accommodative strain eliminated, *i. e.*, the *refraction* should be corrected as accurately as possible. If the error, whether over-correction or under-correction, left by the operation, is small, the eyes may eliminate it by simply practising in the way above indicated without artificial aid. Whether this is going to be so or not, we can judge from our daily measurements of the heterophoria. If not, that is, if we find that the residual deviation remains stationary or tends to increase, or if it is very large, at the outset, we then try to supplement the automatic action of the eyes by *appropriate exercises*.

Thus suppose that after a tenotomy of the left internus we find an esophoria of 3° or 4° left. This is an amount that our experience in such cases shows us will probably increase by several degrees during the process of healing. If we do not feel justified in extending the effect of our operation by further tenotomy, we will immediately begin exercising the eyes, once or more times daily, according to circumstances, by practising the divergence with prisms, base in, and

[1] Read before the Section on Ophthalmology and Otology, New York Academy of Medicine, March 19, 1900.

by making the eyes execute strong lateral movements to the left. Similarly, if after a tenotomy of the right externus there remains an exophoria of the smallest amount, an exophoria that we are morally certain will increase, we practise the convergence by the systematic daily use of prisms, base out, and by making the eyes converge upon very near objects; and we further stretch the divided tendon by making the eyes execute lateral rotation movements to the left.

Similar principles of treatment obtain if after an operation we have, instead of an under-correction, as in the examples cited, an *over-correction*, so great that we think it necessary to reduce it. No specific rules can be laid down for such cases. In each, we judge by the progress made from day to day, and, by the results of our measurements from day to day, how far to push our exercises and when to stop them altogether.

Exercises of this sort made with prisms must not be confounded with similar exercises made upon eyes in which the tendons are intact. These are different in principle and, in my experience, considerably different in result. When we undertake to cure an esophoria by exercise with prisms, base in, we simply stimulate the diverging power of the eyes and by this means hope to offset the continuing causes that produce the undue convergence. In this attempt we usually —I think it scarcely too much to say that we invariably—fail. But when after an operation for esophoria we exercise the eye with prisms, base in, we aim, not so much to practise the divergence *per se*, as to pull upon the severed and yielding tendon and get it to attach itself a little nearer the right position. And in this we not infrequently succeed.

So, too, exercise with prisms, base out, undertaken for the cure of an exophoria, simply means exercise of the converging power, enabling the patient better to fight against the continuing causes producing the deviation, but not removing these causes themselves in their entirety. Such treatment is very often disappointing. But when we exercise the eye with prisms, base out, after an operation for exophoria, we then make the eye pull in against a divided tendon, and aim to stretch the latter so as permanently to affect its place of attachment. This is a procedure much more likely to be successful.

The same procedure and the same class of exercises that are of use in supplementing operations for esophoria and exophoria are equally applicable to *vertical deviations*. Indeed, experience has convinced me that the tendency to spontaneous correction after operations on the vertical muscles is even stronger than in operations on the lateral muscles; and the after-treatment is more important as yielding results that are apt to be both more permanent and more satisfactory.

When the amount of post-operative deviation, especially if it is an under-correction, is very large, little is to be expected either from attempts to get the eyes to perform binocular vision spontaneously or from exercises with prisms. It is best, then, *to modify the operation* by any one of the well-known surgical procedures in order to get a closer approximation to the true correction, before proceeding with the exercises. When such an extension of the operation would seem to hamper too much the mobility of the operated eye, it is better to operate on the other eye and secure the desired effect from that. If, however, the original operation is carefully performed and is checked by rigid quantitative tests, made at intervals during it and directly afterward, there should not be in most cases such a large residual error as to require much subsequent operative readjustment.

The *duration* of the treatment will vary much in the individual cases. Perhaps two weeks may be stated as the average time of active treatment with exercises. During the first week the patient is seen and examined every day; during the second week, every day or every other day, according to circumstances; after that at longer intervals, unless there is some special indication for seeing him oftener, such as the presence of a large deviation or the recent performance of a secondary operation. In any event, it is advantageous to keep some sort of supervision over the case for a month or more after the operation. After the first few days, much of the exercising may be entrusted to the patient himself, if intelligent; but even then the progress of the case ought still to be constantly watched, and daily tests made to gauge the results of the treatment.

Of course, the likelihood of success is much enhanced if the patient starts with good binocular vision. Hence, as many have realized, one important element in the treatment consists in training the patient before the operation *to recognize diplopia and to see binocularly* if possible. With care and patience this may often be effected even in apparently unpromising cases. The various well-known expedients for differentiating the double images, and thus enabling the patient to recognize them better, may be used, the only proviso being that they are used repeatedly and systematically. Such expedients are the red glass and particularly the Maddox rod placed over either eye; or a strong convex glass placed before the better eye to reduce the distinctness and change the character of the image formed by it. Prisms that only partially correct the deviation are often useful. Such a prism may make double images, recognizable either because it brings them close together when they were previously too far apart to be perceived, or simply because it gives them a relation different from the one to which the patient is accustomed. This is particularly the case if we employ, one after another, prisms of different strengths. This causes a changing diplopia, which, as experience teaches us, is harder for the patient to ignore than is a diplopia that is constant. We all know how inapt an eye is to ignore the double images produced by a paralysis; the reason evidently being that the diplopia is constantly shifting, so that the patient cannot learn to make allowance for it,

as he can for one that is always the same. We produce a similar effect with our changing prisms.

This training, which is useful before operation to enable the eyes to recognize double images and seek their fusion, is also and to even a greater degree useful after operation. This is a matter that has been so abundantly worked out by many and competent investigators that it seems scarcely necessary to refer to it, except to say that exercises of this sort are not employed so much as they should be, and are rarely initiated at the time when they would appear to be most serviceable, namely, in the first hours and days after the operation, when we are able to modify to the greatest extent the operative result. At this time our other exercises work to produce binocular fixation; and our likelihood of success will certainly be considerably better if we then secure some measure of binocular vision as well.

There is one other point relative to the preliminary treatment to which I should like to advert. This is the practical utility—likewise recognized by a number of observers—of exercising the patient *before the operation in the use of the eye-muscles* themselves. We practise him, that is, with and without prisms, in making divergent, convergent, and lateral movements, until he acquires as fair a degree of facility as the ocular conditions will allow. This practice will enable him to pursue his post-operative exercises to much better advantage.

To recapitulate, the principles of treatment here advocated are as follows:

First, the patient is *prepared for the operation* by repeated exercise of the eye-muscles and by repeated attempts to secure binocular vision and the recognition of diplopia. This may take but a few days or it may require a week or more.

Second, the operation, however performed, is *checked* all during its performance and immediately afterward by careful tests calculated to show the precise amount of deviation present at each step of it.

Third, *immediately after* the operation the patient is allowed to go about as usual, is encouraged to use his eyes for distant vision, and is urged to practise both eyes together for all ordinary looking. This practice is kept up daily, and daily tests are also made of the amount of deviation. If this is large and is not diminishing satisfactorily, exercises are instituted to stretch the divided tendon, so as to secure its adhesion in a better situation than where it was left by the operation. These exercises are particularly necessary when the operation has left an under-correction.

No bandage is applied, and deep sutures are avoided when possible. I generally instil a sterile salt solution or preferably a weak solution of sublimate, as the latter, it seems to me distinctly promotes the healing of the wound.

It will be observed that I have not mentioned as part of the post-operative exercises the *occlusion* of the better eye and the systematic practising of the amblyopic eye in monocular vision. In fact, I do not think that this procedure should find place until the eyes have first been thoroughly trained in binocular vision or, at least, in binocular fixation. Hence I should prefer to reserve the use of this expedient until a period some considerable time after the operation.

What *objections* are there to the method of treatment here outlined? The first that naturally suggests itself, *viz.*, delay in healing and the risk of exciting inflammation of the wound, is not in my experience valid. These wounds of the conjunctiva and ocular tendons, as is well known, are painless and heal without any inflammatory reaction. As is also known, the parts concerned will stand an extraordinary amount of manipulation without reacting in any way. And certainly the moderate straining and pulling produced by the exercises have never, so far as I have seen, caused any untoward effects.

The danger of *infection* may be urged. But, while conjunctival inflammation or even tenonitis has occurred as a very rare accident after these operations, such an event, as I understand the matter, is ascribable to infection at the time of operation due to contaminated instruments, and not to infection taking place subsequently through the atmosphere. In fact, there appears to be no reason to believe that such accidents are any more frequent with the open method than when an occlusive bandage is employed. At any rate their extreme rarity practically excludes them from consideration, and the added security and permanence of results that accrue from the open method surely more than counterbalance any such remote danger.

A more valid objection is that the patient by sudden movements of the eyes or undue use of them may strain the fibers holding the tendon in place, and produce *an excessive effect*. The likelihood of such an occurrence, however, is more apparent than real. It can practically always be avoided if we take pains to tell the patient just what he can and can not do with the eyes, and insist upon his observing ordinary precautions. If an accident of this kind does happen and if we feel that the over-effect is going to be permanent, we can insert a suture and draw up the retracted tendon. Only, it is to be remembered that such an over-effect if often transitory, and it is well, therefore, to wait a day or two at least before attempting to remedy it with a suture—in the meantime, of course, stopping the exercises or even reversing them.

To conclude: The method here outlined has been employed, either in part or in its entirety, for many years by a number of operators. My own acquaintance with it covers a space of about fifteen years. From that experience I feel sure that this procedure gives greater certainty of results and especially greater stability of results than any other. So persuaded am I of this that I have come to regard the technic of the operation as of subordinate importance. In other words, I believe that we can not hope to effect

an absolute correction by the operation *per se*, however delicately performed. What we can do by the operation is to set the eyes fairly straight and in a position in which, being left free to move, they themselves will work toward an absolute correction. Hence, I say that, provided it is done with care and discrimination, and is checked by precise measurements made during and after its performance, it makes little difference how we do a tenotomy—but it makes a great deal of difference how we treat the eyes afterward.

INTERESTING CASE OF SYPHILIS: EPITHELIOMA.

By L. BLAKE BALDWIN, M.D.,
OF CHICAGO.

Case I.—Man, thirty-seven years of age, American, of German parentage; salesman; unmarried. When seen, November 4, 1899, he presented the following conditions: On the vertex were four ulcers, each two cm. or more in diameter. Over the right supraorbital ridge was an ulcer about 1.5 cm. in diamter. Each of these was covered with a crust from 5 to 10 mm. in thickness. Over the left parietal region was the partially healed remains of an ulcer represented by a cavity about 5 mm. in depth. The entire nose as far back as the bony septum was gone, the remaining portion being a crust barely one cm. in thickness. The left side of the soft palate was entirely gone and the right side badly ulcerated. Upon the right arm was an ulcer about 1.5 by 2 cm. in dimension. The right forearm from above the elbow-joint to the wrist upon its extensor surface presented an almost continuous ulcer. The left forearm presented the same condition excepting that the elbow-joint was not involved. Both thighs, on their external surfaces, from the upper third to the knee presented numerous ulcers, none of them less than 2 cm. in diameter. Upon the inner surfaces there were several. The tibial surface of both legs from the knee-joint to the ankle was an almost continuous mass of ulceration. The calf of the left leg was covered with an ulcer which extended from the junction of its upper and middle thirds to near the ankle and which extended transversely nearly one-third of the circumference of the limb. The right great toe had upon its extremity an ulcer which had progressed nearly to the bone. The second toe of the same foot was covered with an ulcer extending from the base to the tip. The discharge from these ulcers was exceedingly profuse and fetid, so that although the patient lived upon the third floor rear, and the door of his compartment was kept closed, upon entering the hall from the street the odor was sickening. The family, in fact, had been threatened with eviction by the landlord.

In addition to these areas of active ulceration there were upon his trunk the remains, for the most part healed, of over eighty lesions, none of them less than one cm. in diameter and ranging in size from that up to half the size of one's hand. These eruptions had all taken place within the previous fourteen weeks. There were in all 284 ulcers. His emaciation was extreme, his weight having fallen from 178 pounds to less than 90 pounds within that time. The face was colorless; articulation was difficult. Liquid food only could be taken, and that with pain. Unassisted the patient could not lift his head from the pillow. The right hand could be raised to the mouth; the left arm not at all. So great was his weakness that practically no power of movement remained in the lower extremities. His stomach resisted five-grain doses of potassium iodide. He gave a history of chancres seven years previously, which had been cauterized, and, after a few weeks' treatment, having been discharged—cured.

He was placed upon the following treatment: Wet bichloride of mercury dressings were applied to all ulcerated surfaces excepting upon the cranium, and ordered to be constantly kept wet, being renewed once in twenty-four hours. After the first week the wet dressing was applied to the head, but a few days being required to remove the crusts and stop suppuration. Internally he was given the pure juice, seasoned with salt and pepper, of five pounds of beef daily, which amount was increased during the first week to that of eight pounds of beef. He was also given forty grains of potassium iodide, three times daily, the dose being increased during the first week to 115 grains t.i.d.

Following the removal of the crusts and cessation of the suppurative process, the ulcers were dressed with Unna's emplastrum hydrargyri mull. On the eighth day he sat up in bed to eat. On the tenth day he walked with crutches, and on the fourteenth day he walked to his meals unassisted. It is now two months since the first consultation, and he weighs 187 pounds.

Case II.—Woman, forty-one years of age, married, Polish, in America thirteen years. Eleven and a half years ago a pimple appeared upon the left cheek, which gradually extended, spreading over the nose, both cheeks and surrounding the eyes, producing pronounced cicatricial ectropion and leaving white scar-tissue in place of the normal skin. This process from first to last covered about one year in time and was painful and itched. From the face the lesion spread to the right side of the neck where it remained quite stationary for about seven years. During the past three years the activity of the process has been revived and now completely encircles the neck, extending in front of the right ear on to the cheek for about 5 cm. in front of the inferior maxillary angle, and down the sternum as far as the ensiform.

Within the past year a separate lesion has appeared upon the right breast which now measures about 6 by 15 cm. Within the past three months a new lesion has appeared upon the face, commencing as a pimple on the right cheek near

the base of the nose and about 2 cm. below the right eye. From here it has extended to the bridge of the nose in a mesial direction, and as far laterally as the corner of the mouth, and reaching from this point to the lower border of the right eye.

The seat of this lesion is entirely upon the location of the original eruption eleven years ago. Within the past nine weeks a lesion measuring about 6 cm. has appeared upon the abdomen near McBurney's point. About seven weeks ago another lesion, measuring about 4 x 8 cm., appeared on the anterior surface of the right thigh, and within the last three weeks two more lesions, which now measure about 3 cm. in diameter, have appeared in the left inguinal region. The later eruptions have the appearance of fungoid excrescences and are raised above the surrounding tissues from 2 to 5 mm. Looked at from above they have the appearance of a cauliflower mass that has been tightly compressed. For the most part the surfaces of the excrescences are quite flat and even, those on the abdomen are less so and are sunken and irregular in the center.

The older eruptions have less elevation than the more recent ones, but all are distinctly elevated. The color of the later eruptions is light red with a tinge of purple. The one on the face is brownish. They are firm to the touch. Those on the thigh and the neck are very sensitive and painful; those on the neck itch. The others are not painful. About the margin of the eruptions on the abdomen is an area about 1 cm. in width which is dark and angry looking. About the one on the thigh this is less marked; and about the older ones still less so. The original eruption on the face eleven years ago began as a black pimple, with a history of but little discharge. The eruptions on the breast, the thigh, and the abdomen began, in the patient's own words, as "small swellings having a covering like tissue-paper," which broke with discharge of fluid. From time to time crusts have appeared which have dried up and fallen off. At present the application of an oily preparation seems to prevent their formation. There is little oozing. At times there is some fetor. The inguinal glands are not enlarged. The epitrochlear glands are not palpable.

During the past two weeks there has developed anesthesia to touch and pain and some paresthesia in the ulnar region of the right hand, extending from the wrist to the tip of the ring and little fingers. There has developed within the same time tenderness with rheumatoid pains, over the entire left tibia. The patient has borne fifteen children with the following histories: The first died at twelve years of "heart trouble;" the second, at fourteen months, cause unknown; the third is living and well, twenty-eight years old; the fourth died at eighteen years, of "consumption;" the fifth, at sixteen years of "consumption:" the sixth is living and well; the seventh is living and well; the eighth died at six weeks, cause unknown; the ninth died at eighteen weeks, cause unknown; the tenth is living and well; the eleventh is living and well, four years old, the youngest living; the twelfth died at two months, cause unknown; the thirteenth died at nine weeks, cause unknown; the fourteenth died at eight weeks, cause unknown; the fifteenth was still-born (the only miscarriage) three years ago, evidently near term.

There is no history of any sore-throat nor falling of the hair, nor any necrotic ulceration. The lesions have always appeared distinctly raised above the surrounding tissue. The husband came to this country one and one-half years before the wife, but reveals no history of sore-throat, falling of the hair nor eruption of any kind. The patient is well nourished, there being considerable excess of abdominal adipose tissue. She sleeps poorly on account of pain and for the past six weeks has had little appetite.

Microscopical Findings.—Histologically an epithelioma. Atypical epithelial cell-proliferation into the deeper tissues. Sections were stained for tubercle bacilli with negative results. Sections stained by thionin, methylen blue and klebs. Triple stain for protozoa, deeply staining bodies with hyaline rings in epithelial cell-masses, probably protozoa. A few organisms with double contour were present.

CLINICAL MEMORANDUM.

A NEW TRACTION HIP-SPLINT.

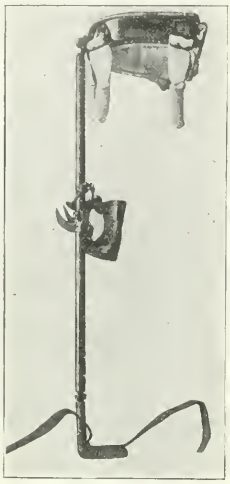
By JAMES K. YOUNG, M.D.,
OF PHILADELPHIA;
PROFESSOR OF ORTHOPEDIC SURGERY IN THE PHILADELPHIA POLYCLINIC HOSPITAL AND COLLEGE; CLINICAL PROFESSOR OF ORTHOPEDIC SURGERY IN THE WOMAN'S MEDICAL COLLEGE, ETC.

The inefficiency of any original appliance is shown by the number of modifications which it has undergone. The long traction splint designed by Taylor and improved by Shaffer has in my hands proved so efficient that modification has seldom been necessary, but the splint here described has been the result of an effort to construct an appliance combining all the good qualities of the better class of long traction splints in a cheaper form. The writer calls it his "Polyclinic hip-splint."

A piece of light gas-pipe is substituted for the hollow steel tube which is ordinarily used for the upright of the splint. Into the upper portion of this a piece is brazed, and perforated so as to attach it to the pelvic band by a heavy screw and two nuts. The waistband is the same pattern as that employed in the more expensive apparatus but of less expensive material, consisting of a band of sheet steel, covered with leather and well padded, with buckles for two perineal straps, and a leather strap completing the circumference. Into the leather end of the tube is inserted a forged foot-piece, the upper portion of

which is cut with threads for two nuts, and the lower end has attached to it a piece of sole leather and a strap to buckle into the leg extension adhesive straps. The foot-piece should be prevented from turning by a screw working in a slot in the front part of the tube. The thigh pad is attached to the upright tube by a sliding steel arm made adjustable with a side screw and having four

Fig. 1.



The Polyclinic Hip-splint.

buckles. The tube may be fixed at any angle upon the pelvic band by means of the tube nuts, and extension may be made from the lower end of the tube by the two nuts.

This brace has been used by the writer for the past two years in dispensary practice and has proven itself cheaper than, and equally efficient with, the more expensive apparatus. It should be used with crutches and a high shoe.

222 South Sixteenth Street.

MEDICAL PROGRESS.

Permanent Artificial Anus.—R. F. Weir (*Med. Record*, April 21, 1900) describes a method of making an artificial anus which is under full control, even to the extent of preventing the escape of gas, and without the use of cumbersome apparatus. The gut is made to come out through the usual opening inside the iliac crest. The lower end is completely severed, closed by sutures, cleansed and dropped back into the abdominal cavity. For the upper portion a canal is made by separating the layers of abdominal muscles out to the iliac crest, where the fascial attachments are divided, and the canal continued subcutaneously to a point two inches behind and one inch below the anterior superior spine, where a second skin incision is made. Through this canal the upper portion of the gut, cleansed and closed, is pulled and sutured to the skin incision just mentioned. The skin incision inside the iliac crest is then closed. The bowel may be kept closed for twenty-four hours to prevent soiling before adhesions occur. No apparatus is necessary. A piece of gauze is laid over the opening and the weight of the clothing gives pressure enough to occlude the bowels as it passes over the crest of the ilium. In certain cases it is necessary to cut the mesentery a little to render the gut sufficiently movable to reach the extra-iliac incision and this cutting does least damage to the arterial supply, when the line of division is parallel to and one and one-half inches distant from the gut.

Castor Oil for Neuralgia.—Neuralgia and tic-douloureux are painful disorders which are often very obstinate and unyielding to any treatment. Harold N. Moyer (*Jour. Am. Med. Assoc.*, April 21, 1900) reports some brilliant results from the use of castor oil in these affections. He has treated about fifteen cases of neuralgia by this method, but only seven of these are reported. Of these seven cases, five were facial, and two were brachial neuralgias, and only one case failed to improve under the administration of the castor oil. One of the cases of brachial neuralgia was very severe, and various remedial measures had been employed without result. This patient was given a large dose of castor oil at noon, three hours later the pain had greatly decreased, and the following morning it had disappeared entirely. The patient took several more doses of the oil, but the pain did not return. Two weeks' treatment with castor oil cured an acute case of facial neuralgia. In one case of tic-douloureux, which had lasted for 17 years, the administration of the oil was followed by an immediate improvement of the pain. The spasms continue and there are occasional twinges of pain, so that the patient cannot be said to be cured, but the pain is so much less severe that the patient is more comfortable than he has been in years. Another case of facial neuralgia, which had lasted for five or six years, was cured at the end of one week of the castor-oil treatment and there has been no return of the pain. Six doses of castor oil cured a supra-orbital neuralgia, which had lasted for nearly fifteen years. In the case which was not benefited by this treatment, a mixed astigmatism and well-marked eye-strain were discovered. The writer administers the oil in from one- to two-ounce doses every morning before breakfast until relief from the pain is obtained. The oil should be "washed" and a few drops of essence of anise added to each pint. The best method of taking the oil is to stir it up in a tumbler with two or three tablespoonfuls of ale. He recommends Dogshead or Bass' ale, as they contain a large quantity of gas, and says that if the

oil is taken in ale thus, it makes an emulsion with the ale and cannot be tasted. After the first doses the oil seems to lose a good deal of its cathartic power. The writer does not explain how castor oil acts in relieving neuralgia, but says that it is not due to its cathartic action. He discusses briefly the physiologic action of the drug, which is not as yet definitely determined.

Intermenstrual Dysmenorrhea. — The phenomenon of intermenstrual dysmenorrhea, if mentioned at all in text-books, is stated to be rare. Malcolm Storer (*Bost. Med. Surg. Jour.,* April 19, 1900) has observed this phenomenon in no less than 20 out of 400 cases. He presents notes of 20 cases of his own, and on these and 25 additional cases collected from literature, he makes the following observations: (1) The pain appeared with regularity in all the cases, practically every month except when pregnancy was present. In 22 cases the pain always occurred on a certain day from the beginning of the last menstruation. There was a variation in 13 cases of two days, and in 4 of four days. In 2 cases of irregular menstruation it appeared on a certain day before the beginning of the next menstruation. (2) In 37 out of 41 cases the pain appeared on from the twelfth to the sixteenth day, counting from the first day of the previous menstruation. In 20 cases it appeared exactly on the fourteenth day. In 2 cases it began on from the seventh to the tenth day, in one on the seventeenth, and in one on the eighteenth day. (3) The character of the pain was paroxysmal in a large number of cases, the attacks coming either at intervals of several hours, or else there was a constant pain with marked exacerbations, subjectively much like labor pains. The pain resembles that of menstruation in about one-half of the cases; in the others it was "entirely different." (4) The pain reached its maximum on the first or second day, and lasted in 10 cases two days, in 9, three days; in 8, one day, and in only 4 did it last four or more days. (5) The site of the pain in 14 cases was limited to one side, in 2 it alternated, and in 12 it was more general. (6) The pain was not accompanied by a discharge like that of menstruation in any of the cases. For this reason the writer objects to the term "intermenstrual dysmenorrhea." In 10 cases, however, there was a marked increase of leucorrhea, indicating congestion. In considering the etiology of this pain, Storer discusses the following theories which have been advanced: (1) The mechanical theory—tubes, ovaries; (2) the neurosis theory; (3) the intermenstrual cycle of congestion theory; (4) the intermenstrual cycle of ovulation theory. Not believing any of these theories to be entirely correct, the writer offers the following theory which he calls the "awakening of menstrual activity" theory. This intermenstrual pain comes on about the fourteenth day after the beginning of menstruation, which is the nineteenth after the climax of Stephenson's wave. Therefore it occurs just about the time the pressure line has reached its lowest point. If we then suppose that the intermenstrual wave, if one exists, is one of preparation rather than of subsidence, in which nature, suddenly awakening, begins to make ready for the coming activity, whether menstrual or ovarian, the readjustment of forces might account for the occurrence of this pain. This theory, the writer thinks, would not be incompatible with the fact that this pain occurs under such a variety of pathological conditions. He cites several cases showing that the pain has more relation to the coming menstruation than to the previous one.

Intestinal Suture.—W. Edmunds and E. C. Stabb (*Lancet,* April 14, 1900) performed experiments in circular enterorrhaphy. They used three different methods: Halsted's inflated rubber cylinders; Murphy's button; and Laplace's forceps. Seven trials of each method were made on dogs. All cases by the Halsted method were successful, only five by the Murphy button, and four by the Laplace forceps. The inflated rubber cylinder pushes back the mucous membrane which otherwise always interferes with suturing the outer coats, especially the peritoneum. At the same time it prevents the outflow of intestinal contents so that no clamps or ligatures are necessary. Murphy's button is not always trustworthy unless reinforced by external sutures, the placing of which lengthens the operation materially. Recovery is not so rapid after Murphy's button. After Halsted's method formed stools appeared next day; after Murphy's button formed stools occurred only after three or four days. Laplace's forceps are of little assistance.

Dormiol as a Hypnotic.—In order to satisfy all the requirements of a good hypnotic, a drug must be effective in all cases of insomnia irrespective of cause; it must be cheap, of fair taste and unaccompanied by sequelæ. R. Peters (*Münch. med. Woch.,* April 3, 1900) thinks the dormiol satisfies all these requirements to a high degree. It is a combination of chloral and amylenhydrate, occurring in form of an oily, camphoraceous liquid which can readily be given in capsules or in form of a ten-per-cent. aqueous solution. In the sleeplessness of functional and organic nervous diseases, as well as in pulmonary, cardiac, intestinal and nephritic lesions, its action has been uniformly good. After doses of 7.5 grains a more or less deep sleep will follow in one-half to one hour, and it is but seldom necessary to increase the amount up to 15 to 30 grains. As in other hypnotics, a certain degree of tolerance is established after a while.

Infantile Diarrhea.—W. E. Fothergill and J. Penny (*Med. Chron.,* April, 1900) report the observations on 71 cases of infantile diarrhea appearing in dispensary practice; 11 cases died, the remaining 60 recovering on salol or petroleum alone, the diet being an ordinary one suitable to the child's age. Salol was given in powder in 36 cases; half a grain every three hours was the min-

inum dose and three grains every four hours, the maximum dose. Salol did not allay the vomiting and even proved irritant in many cases. The cough which so frequently is present was not appreciably influenced. Salol was, therefore, found to be a valuable intestinal antiseptic, but should be given to children not more than once or twice daily, and mixed with some demulcent. Petroleum was used in 34 cases, the preparation being an emulsion containing 33 per cent. of petroleum. The usual dose for child one year old was one dram three times per day. In all but two cases the results were satisfactory. No derangement of stomach was noticed, the vomiting usually stopping before the diarrhea. The movements rapidly resumed their normal smell, color and consistence. The bronchial catarrh was obviously improved in many cases. It is not probable that petroleum undergoes much change in the system since nearly all of it can be recovered in the feces. Bismuth may be combined with the above and calomel or hydrarg. cum creta seem to act better when followed by a few doses of petroleum.

Continuous Use of Digitalis.—J. Groedel (*Practitioner*, April, 1900) discusses the conditions of the heart in which he believes a continuous use of digitalis is sometimes indicated. He believes firmly in the physical and dietetic method of treatment of chronic disorders of the circulation, but urges the benefits derived from digitalis in many cases where internal medication is necessary. In the majority of heart diseases there comes a time when lasting compensation cannot be produced by rest, baths, gymnastics, or short courses of medicines. He believes that, instead of waiting for symptoms of incompetence, such as diminished diuresis, accumulations of fluid and dyspnea, it is much better to use digitalis at regular intervals, say four to eight grains one day a week or perhaps less frequently. In this way compensation may be preserved for a long time, and although finally the effect is lost and death results, yet the comfort of the patient is much enhanced in the meantime. Although the cumulative effects of the drug are to be avoided, the author has seldom seen a well-marked case of toxic symptoms referable to the heart. Secondary effects, such as nausea and flashes before the eyes, are more frequent and act as warning signals, especially when the pulse becomes irregular after only small doses. By observing diuresis dangers of cumulation may be avoided, for, if the urine is not increased after its use for several days, the drug must be stopped. The assertion that digitalis produces a rapid decline of strength is denied by the author who claims that this is due to the disease for which digitalis is taken. He further believes that the body does not become inured to the remedy and thus less effected by its administration. Mitral insufficiency is the lesion which is naturally most benefited by digitalis, but he believes that no entire class should be excepted, especially when no contraindications, such as great tension or an individual repugnance, exist. In cases of slight fatty degeneration in which the muscle is still capable of repair, continued use of digitalis oftentimes proves successful.

Constitutional Causes of Catarrhal Affections.—Catarrhal conditions of the upper air passages are so common and their treatment oftentimes so unsatisfactory, especially in this climate, that it is extremely important to discover the underlying cause which predisposes to the local condition. W. A. Wells (*Med. Record*, April 21, 1900) gives a valuable résumé of the constitutional affections which are liable to cause these catarrhal lesions and the treatment which he has found most successful. He believes that the local trouble may be considered secondary to the systemic disease when: (1) No adequate local cause is apparent; (2) direct local treatment has failed; (3) the catarrhal inflammation has manifested itself after the coexisting trouble; (4) catarrhal inflammations appear in other parts of the body; (5) the supposed cause is sufficient to produce these local effects; (6) and when treatment of the associated condition improves the local catarrh. It is believed that cutaneous eruptions, such as herpes, urticaria and pemphigus may appear as true reflex neuroses of nasal origin and on the other hand may act as the primary cause of the nasal trouble. The gastro-intestinal tract is, no doubt, responsible for much of the nasal catarrh and he recommends a careful consideration of it in all obstinate cases. Pepsin, hydrochloric acid and nux vomica are often very effective when given after meals. Intestinal obstipation is important and is most satisfactorily relieved, according to some authors, by sulphur. Intestinal flatulence is best relieved by regulation of the diet, massage and exercise, combined, if necessary, with such medication as: pepsini pur. and pancreatin ext., aa gm. ii; pulv. carb. liq., and bism. subgallate, aa gm. iv. M. Fl. chart. xii. S. One before meals. Cardiac lesions frequently cause a local engorgement and must be carefully examined for. Movable kidney and affections of the reproductive system of the female are sometimes responsible for sympathetic conditions in the nose and throat. Hysteria often aggravates a local inflammation and while topical treatment is being employed the hysterical state is perhaps best influenced by such methods as electricity, balneology, change of environment, and separation from too sympathetic friends. The gouty or neuro-arthritic diathesis no doubt plays an important rôle in many obstinate throat conditions and has fairly characteristic manifestations. The soft palate, fauces and posterior walls of the pharynx present a highly engorged condition approaching bagginess. Intense redness, pain in throat, difficulty in swallowing and soreness in the cervical muscles are usually present. The larynx becomes involved and gouty deposits are found in the crico-arytenoid joints and the true vocal cords. Locally, thiol, two to four per

cent. in glycerin, is valuable, but the general condition must be improved by the salicylates, iodides and the alkaline treatment. Stress is also laid upon the sympathetic diathesis by which is meant the disposition to the origin of reflex disturbance in various parts of the body, shown so frequently by the attacks of hay-fever, migraine and asthma, etc. Too much importance oftentimes is attached to the local condition, the underlying morbid state, due probably to a vasomotor causation, being overlooked. The sedative or motor depressant drugs are most in vogue, such as bromides, opium, chloral, amyl nitrate and nitroglycerin. For hay-fever, in addition to the local treatment, he recommends:

℞ Zinc phospt. .....gr. $^1/_{16}$
Quinine sulph. .....gr. ij
Ext. belladonnæ .....gr. $^1/_8$.
S. One pill before each meal.

Neurasthenia, no doubt, oftentimes prepares a ground of such sensitiveness that a minimum change shall give rise to maximum symptoms. Rest, massage, electricity and change of environment are important. The glycerophosphates perhaps are the most efficacious drugs for internal medication in neurasthenic cases.

Purulent General Peritonitis.—F. Bode (*Mitt. aus den Grenzgebieten der Med. u. Chir.*, 6. Band, p. 286) says that the general peritoneal cavity is roughly divisible into four cavities, an upper, from the hollow of the diaphragm to the level of the navel where the anterior abdominal wall closely approaches the posterior forming a strait, a right and a left cavity, comprising each iliac fossa and bounded internally by the anterior border of the psoas muscles, and, finally, an inferior cavity, comprising the true pelvis and the space above it between the two psoas muscles. The arrangement of the boundaries and contents of these spaces determine the natural walling off of abscesses within them from the general peritoneal cavity. Such occurrences are common in appendicitis, in diseases of the uterine adnexa, in those of the stomach, duodenum and gall-bladder, and furnish the first hint in the treatment, namely, thorough drainage of each cavity with reference to its usual boundaries in cases of general peritonitic infection. The second indication is the complete irrigation of the affected local or general peritoneal cavity with salt solution at the time of operation and thereafter by permanent irrigation, if necessary, both to wash away the exudate and to prevent undue adhesions. The hindering of these unnecessary adhesions is at least for a time provided for also by leaving considerable solution in the cavity at the operation. By such constant flow or frequently repeated flushing and a carefully planned drainage of one pocket into the others, the pus is mechanically removed and tends to settle in the depths of these four recesses whence drains take it to the surface of the body. The method of procedure is as follows: When the peritoneal cavity has been opened without respect to the light adhesions, all the movable intestines are eventrated and washed and search for and treatment of the perforation or other cause of the disease made. Likewise careful attention is given to cleanse and dry all depths of the cavity, those of the pelvis, about the liver and spleen, etc. The quantity of solution is 30-40 quarts at a temperature of 105-115° F. Peristalsis is promoted and shock combated by the treatment, notwithstanding the manipulation. The eventrated intestines are next replaced. Then a long fenestrated rubber drain-tube is carried through the base of the mesentery, curved on itself along each side of the vertebral column and passes over the colon through a secondary opening in each flank. Other drains are carried through the lateral incisions into each iliac fossa and through the original median approach to the environments of the liver, stomach and spleen. Under continuous current of salt solution to drive out the air the incisions are narrowed by layer sutures as much as possible. The potency of all the tubes is tested. Copious dressings are now applied and the patient put to bed with head and trunk elevated to promote gravitation of the exudate downward to the drains. Then a thorough flushing out of all the tubes with 1000-1500 c.c. of warm salt solution was done two or three times daily, attaining cleanliness, stimulating peristalsis, promoting defecation, and preventing collapse. The results quoted are all good. Upon the cadaver irrigation through similarly arranged tubes with colored fluid was shown to be far-reaching and efficacious.

Bacteriology of the Gall-Bladder.—Dr. L. von Mieczkowski (*Mitt. aus den Grenz. der Med. u. Chir.*, 1900, p. 307) says that he has established the fact that in healthy animals the contents of the healthy gall-bladder, hepatic and cystic ducts are usually sterile, while those of the distal, *i. e.*, intestinal, end of the common bile-duct are very commonly infected from the cavity of the duodenum. In man he has confined his observations to the gall-bladder during laparotomies. Here he finds sterility always present in health and even in cases of cholelithiasis not associated with inflammatory complications. The reaction of the bile was commonly feebly alkaline or neutral. He also found that fresh human bile is only imperfectly germicidal, permitting the staphylococcus pyogenes to proliferate rapidly and the bacillus coli communis almost unhindered. The normal sterility of the gall-bladder contents and of the proximal ducts may be explained by the force and direction of the flow, which sweeps back into the intestine any germs which may tend to invade more than the distal end of the common duct. When bile stasis in disease occurs, this cleansing current is stopped and germs promptly invade the proximal ducts and the bladder, especially the bacillus coli. Such cases of cholelithiasis as are sterile may be explained by the pouring out of sterilizing fluids into the bladder during the acute stage, which either totally or partially destroy the bacteria. Experiments with

animals also showed that fatal peritonitis occurred more often when the contents of the infected bladder were thick and imperfectly absorbable than when thin and more readily taken up by the lymphatics.

Tannopin.—There is a great advantage in combining tannin with other compounds which allow it to pass the stomach unaltered, but the effect is heightened if at the same time an antiseptic is set free. Tannopin or tannon, a combination of tannin with urotropin, is one of the most reliable of this group according to E. Doernberger (*Münch. med. Woch.*, April 3, 1900). Small children take doses of 7.5 grains without abdominal discomfort or other undesirable symptoms. It is necessary to continue the drug some time after the acute or chronic diarrhea has abated to guard against relapses. The only disadvantage is the expense.

Cause of Xerosis Conjunctivæ.—It has recently become the prevailing opinion that xerosis and keratomalacia are bacterial affections; a view supported by the fact that numerous micro-organisms have been isolated from the conjunctiva. M. Radziejewski (*Therap. Monatshft.*, April, 1900), however, thinks that the primary lesion is due to a nutritional disturbance which creates a *locus minoris resistentiæ* and thus explains the bacterial flora found. There generally is no uniformity as to the number and variety of bacteria present; thus in addition to the xerosis bacillus, streptococci, staphylococci, pneumococci and others have been encountered. As to treatment, in addition to tonics, frequent irrigations with chlorine water, hot poultices and the application of iodoform are recommended, with later the continued massage with yellow oxide of mercury ointment.

Itrol in Diseases of the Skin.—Not only in gonorrheal and other venereal troubles has this citric acid salt of silver given evidence of its therapeutic value, but also in affections of the skin is its worth highly lauded by O. Werler (*Wien. klin. Rundschau*, April 1, 1900). The methods of application of itrol are the following: (1) In a solution of 1-10,000 up to 1-4000 for wet dressings, irrigations, etc.; (2) in powder form; (3) as itroltalcum in one-half to five per cent strength; (4) in vaseline up to a strength of two per cent; (5) in pencil form in one to two per cent. strength, mixed with ol. cacao in a base of cera alba. Itrol answered in all cases where an antiseptic and disinfecting medium was called for. It acted in a mild, but efficient manner and was entirely harmless to the patient. No irritation of the skin followed its use. No idiosyncrasy for the remedy was discovered in any of the patients. It is only necessary to begin the use of itrol with small doses, gradually increasing them, to insure entire freedom from pain and a possible local irritation.

Formalin Alcohol in Night-Sweats.—At a meeting of the Berliner Medicinische Gesellschaft (*Berlin. klin. Woch.*, April 9, 1900), H. Hirschfeld read a paper on the success attained in phthisical night-sweats by the use of a mixture of formalin and alcohol. The method is as follows: A mixture of equal parts of formalin and absolute alcohol is applied by brush or cotton wad to those parts of the body subjected to the sweats. Caution must be observed, however, in order to prevent the patient from inhaling the formalin vapors; for should this occur, the breathing becomes oppressed, the nasal and pharyngeal mucous membranes become irritated, tendency to cough results, the eyes become inflamed and the patient is thereby made miserable. To prevent all this, Hirschfeld provides himself with gutta-percha tissue—about a square yard—which he wraps around the patient, the latter being covered only by an undershirt. This envelope is slightly lifted while the brush moistened with the formalin alcohol is applied to the back. Then the patient is told to lie on his back, the shirt and gutta-percha covering the chest and abdomen are raised, and the same application made here. It must be carefully done and all crevices where the formalin vapor might escape, *e. g.*, about the neck or the waist, must be closed by means of cloths covered with the gutta-percha tissue. Then the patient is covered with the bedclothes and remains so for one hour. After that time the formalin vapor has disappeared from the skin and the rubber tissue may be removed. When done thoroughly and carefully, not a trace of the vapor reaches either eye or respiratory apparatus. In some case, one such treatment is all that is necessary to prevent the sweats for many weeks. In others it happens that after two, three or four weeks a second procedure is called for. It is only in the most stubborn cases that a second or a third treatment within a week may be necessary. As for the power of the skin to withstand the formalin when applied over a course of some little time, Hirschfeld says that he met only occasionally with disagreeable results. Once, an urticaria; twice, slight erosions, and at times a scaling of the epidermis were the chief effects. He now paints the back, chest and abdomen in one sitting, leaving the arms and legs for another. It is to be observed that the formalin is not to be applied to parts which may have wounds or erosions; nor to parts which have recently been covered with mustard plasters or painted with iodine; nor to the nipples and navel, the genitals and the arms. A slight burning sensation follows the application of formalin, especially in delicate skins. Such cases should be treated with a weaker solution of formalin than ordinary ones. Under no condition should the formalin be entrusted to the patient's care or use. Grave results can be occasioned thereby. The final words to be said for formalin are: (1) It is superior to all other anthidrotics in its certainty of action and its promptness; (2) in the length of time over which it produces its effect; (3) all other remedies are superfluous. There is no doubt in Hirschfeld's mind that formalin has gained a high point in phthisiotherapy.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 Fifth Avenue, New York.

Subscription Price, including postage in U. S. and Canada.

Per Annum in Advance	$4.00
Single Copies	.10
With the American Journal of the Medical Sciences, Per Annum	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, APRIL 28, 1900.

THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Before the appearance of our next issue the Fifth Triennial Session of the Congress of American Physicians and Surgeons will be held in Washington. The program of this session has been more wisely arranged than formerly in that it is designed to attract the members of the constituent societies to the meetings of the Congress. Instead of an effort to present elaborate, epoch-making theses, the general subject of "Bacteriology in Health and Disease" will be presented in its various aspects by a series of short papers. This is eminently wise, as it gives great variety to the program and adds to the interest by the number of speakers that will appear.

The first session of the Congress, which will be held Tuesday afternoon, will be occupied by this discussion, while that of Wednesday will be devoted to two addresses on topics of general interest, and a poem by Dr. S. Weir Mitchell. In the evening of that day Dr. Henry P. Bowditch will deliver the presidential address upon "The Medical School of the Future."

The programs of the constituent societies set forth a veritable feast of medical lore and discussion. More time than formerly will be allowed these, the meetings of the Congress being limited to the two sessions of Tuesday and Wednesday afternoons. The social functions have not been neglected, and invitations to private dinners, luncheons, etc., will reach their climax in the banquet on Thursday night. The Medical News of May 5th will present a complete but concise report of the entire meeting, together with some of the most important addresses and essays.

PROPHYLAXIS OF CHILDREN'S DISEASES.

We are getting ever farther and farther away from the idea, once so prevalent, that the so-called "ordinary diseases of childhood" are practically inevitable. While the most careful precautions are necessary to prevent the spread of measles, scarlet fever, and whooping-cough, the problem of their prophylaxis is by no means hopeless of solution. School inspection has in recent years made it clear that the prevention of the spread of infectious disease among the children of a neighborhood is only a matter of exact segregation. It remains now for the family to demonstrate that even when a contagious disease has entered a household, it is by no means a foregone conclusion that all of the susceptible members will be attacked. This is already a happily accomplished fact in the practice of many physicians.

It has been often said that scarlet fever is intensely contagious. It is true that the germs of the disease retain their virulence for a long time and outlive seemingly unfavorable conditions, such as long transportation in letters. The disease does not spread, however, except by direct contact with material from a scarlet-fever patient. As for whooping-cough, attention has been called in France to the fact that the mere separation by the corridor of a hospital of those suffering from the disease, and the prohibition of the passage of attendants from an infected to an uninfected ward are sufficient to prevent the spread of the disease. In measles segregation precautions to be effective must begin early and must be very carefully enforced. Even against its eminent contagiousness, however, a barrier can be placed much more effectively than formerly because of the help that Koplik's spots afford in the early diagnosis of the disease.

All of the diseases of children are worthy of respect in this matter of prophylaxis. Even mumps and chicken-pox may give rise to compli-

cations in the joints, kidneys or heart, that will seriously interfere with subsequent good health, and make the patient much less resistant to disease later in life.

Now that schools are becoming less a factor in the spread of contagion, the physician himself must take additional precautions that he, in the course of professional work, does not prove a source of contagion. The practice of wearing a long washable overgarment while attending cases of contagious disease is no longer merely an extraordinary precaution to be taken in better class families. It has become a plain duty for the physician in all cases. Children can, without doubt, be guarded effectively from all contagion until such time as their resistive vitality will protect them. Freedom from the contagious diseases of childhood will often mean perfect health for the individual up to adult life, while, as is well known, these diseases often leave their "marks" on developing adolescents. Damaged constitutions result that prove an easy prey to typhoid or pneumonia or insidious tuberculosis.

THE AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION AND THE PATHOLOGICAL INSTITUTE OF THE NEW YORK STATE HOSPITALS.

If we give a rapid but critical glance at the vast field of psychiatry, we are struck by the significant fact that but few epoch-making works commensurate with those presented in other fields of enquiry are to be found. In the progress of physiologic, biologic, psychologic and medical sciences, psychiatry and especially psychopathology, that is, the science of abnormal mental life in general, have no doubt had their share, but that share is small, compared to that of other sciences. General laws, the essence of all science, are conspicuously absent in the province of psychiatry and a well-established and generally-accepted theory guiding psychiatric practice is as yet unknown.

What may possibly be the cause of this lagging of psychiatry behind all other sciences? Is it that psychiatrists care not for scientific progress? Is it that psychiatrists do not realize the modern point of view that theoretical science is an indispensable requisite of applied science? To these questions the answer must be favorable to the profession. The psychiatrists do care for scientific progress and do realize the importance of theoretic research work. Where then lies the cause of the slowness of psychiatric progress? It lies partly in the extreme complexity of the science and partly in the lack of organized scientific investigation to work out results that are otherwise inaccessible to individual efforts. Psychiatry is far more complex than all other medical sciences, because, in addition to physical processes, psychic activities and their symptoms must be investigated. It is from this standpoint that more united efforts are required to make a successful start on new lines of research. What still more retards the growth of psychiatry is the fact that, although being the most complex of all medical sciences, it lacks central laboratories for special scientific research. And when such a laboratory is accidentally established with some degree of success, an asylum superintendent, who has but a faint conception of scientific work and of the spirit of toleration, tries to lay violent hands upon it and suppress it.

In our country, in the State of New York, a research center, the Pathological Institute was established for investigation of insanity along many lines of research. Instead of having the support of all interested in psychiatry, asylum superintendents in the function of commissioners, committeemen and hospital managers have been first and foremost in attempting to cripple it and stifle the very spirit of its work.

We must not, however, accuse all psychiatrists indiscriminately. For after all such destructive tendencies are confined to but a small portion of the profession, a portion that is used to authority, to order about, to command and to dictate. Unfortunately, science cannot be directed by mandates and ordered about. Science flourishes in freedom.

The issue now is, shall psychiatry be independent or shall it move, live and do the bidding of commissions, committees, and asylum managers? The question is a vital one. For it means the life of psychiatry as a science; it means the life of psychiatry as an American cultivation. It is to the honor of the United States that such an institute of wide scope was first established on American ground. Will the American Medico-Psychological Association permit an outrage on psychiatry in general and on American psychiatry in particular? Will the American Medico-Psychological Association let the reproach fall on it that it witnessed with equanimity, with indifference, the destruction of a psychiatric institute without raising even as much as a protest in its defense? The American Medico-Psychological Association, if we understand it aright, is for the

maintenance of the interests of psychiatry; it is, moreover, the guardian of American psychiatry. Will not then the Association stand firmly by psychiatry as a science and deprecate and denounce all those who want to regulate psychiatry by mandates, edicts and bulls? Will the psychiatric profession and the American Medico-Psychological Association in particular let the charge fall on it that it permitted scheming personalities and unrestrained individual jealousies to undermine a scientific research center of much promise, a center which European authorities recommend to their own countries as a worthy model?

ECHOES AND NEWS.

NEW YORK.

Hospital for Sick Animals.—The Commissioners are constructing a hospital in connection with the Central Park menagerie for sick animals. The hospital is designed more especially for sick deer, but a part of it will be set aside for the feline species.

Crusade against Spitting.—Dr. Robert A. Black, chief of the Health Department of Brooklyn, has begun active steps in enforcing the law against expectorating on the floors of public buildings, ferry-boats, or street cars. Two men were arrested April 11th on the street cars for spitting upon the floor. The penalty for breaking this ordinance is a fine ranging from $1.00 to $250.00. An arrest was also made the same day upon the Third Avenue Elevated Road.

Gift to Mt. Sinai Hospital.—Meyer Guggenheim and his sons have given $200,000 to Mount Sinai Hospital. The money is to be used to erect a hospital building in the group to be built in Fifth Avenue between One Hundred and One Hundred and First Streets. The new building will be erected as a memorial to the deceased wife and mother of its donors. The structure will be set apart solely for private patients.

Nicoli Dead.—The acrobat Nicoli, who, in attempting a triple somersault in one of the New York theaters last week, fell and dislocated one of his cervical vertebræ, died April 23d. An operation was performed at Bellevue Hospital to relieve the pressure made upon the cord by the sixth cervical vertebra, and it was believed at one time that the patient would recover, but he gradually succumbed.

Anthropology at the Barge Office.—Professor Ripley and ten post-graduates at Columbia University made a descent recently upon the Barge Office (immigrant quarantine) in search of interesting specimens. Their careful measuring of skulls and their fluent talk concerning the Retzius principle of measurement of dolichocephalic, brachycephalic, and mesocephalic craniums created no little excitement among the bewildered immigrants.

Contagious Diseases.—For the week ending April 12, 1900: Measles, 716 cases and 27 deaths; diphtheria, 240 cases and 55 deaths; laryngeal diphtheria (croup), 18 cases and 5 deaths; scarlet fever, 176 cases and 18 deaths; chicken-pox, 14 cases and no deaths; tuberculosis, 201 cases and 182 deaths; typhoid fever, 7 cases and 3 deaths; cerebrospinal meningitis, 10 deaths; totals, 1372 cases and 300 deaths.

Dr. Jacobi Honored.—A number of friends, professional associates and admirers of Dr. Abraham Jacobi have arranged to celebrate his seventieth birthday by giving him a dinner at Delmonico's on the evening of May 5th. This is recognition of the high esteem in which Dr. Jacobi is held personally and of the valuable services he has rendered in various relations during the course of his career of almost fifty years as a physician, educator, and civic worker. In accordance with a long-established German custom, it is the intention of those having the matter in charge to publish a "Festschrift," that is, a series of papers by representative men, setting forth the present status of science in the various departments of medicine. The affair is not exclusive in any particular; application blanks for a seat at table can be secured by addressing Dr. A. G. Gerster, Chairman, P. O. Box 3032, New York City.

New Genito-Urinary Organization.—A number of the leading genito-urinary specialists of this city have formed a society to be known as the New York Genito-Urinary Society. It will meet monthly, when cases will be reported and papers read on different branches of the specialty. The office-bearers are: President, Dr. Ramon Guiteras; Vice-Presidents, Drs. Winfield Ayres and Otis K. Newell; Treasurer, Dr. George W. Blanchard; Secretary, Dr. A. D. Mabie; Corresponding Secretary, and Stenographer, Mr. Samuel Bennett, 161 Garfield Place, Brooklyn, from whom information as to terms of membership, etc., may be obtained. Correspondence is invited with specialists in other parts of the country and abroad.

Ambulance Wrecked.—A Flower Hospital ambulance, while making a hurry call recently, was wrecked at Third Avenue and Fifty-Eighth Street. The driver, Frank McKenna, and Dr. Peckham, the surgeon, received various scalp and other wounds. They were taken back to Flower Hospital in an ambulance from the Presbyterian Hospital.

Obituary.—Dr. John Habershaw died on April 20th in his forty-sixth year. He was graduated from the College of Physicians and Surgeons and was in active practice. He was widely known socially.

Bellevue's Interpreter.—Joseph Klovetschek,

who was killed on Park Row on April 21st, was unofficial interpreter at Bellevue Hospital. A German by birth, he spoke French, Spanish and Italian, and enough of many Eastern dialects to make himself understood. Greeks, Armenians, Arabs and even Chinamen made themselves intelligible through him.

Hot Air in Bellevue.—The Sprague apparatus for the treatment of rheumatism, sciatica, etc., has been placed in Bellevue Hospital. Air heated to a temperature of 400° F. can be applied to the whole body, while there is a separate apparatus for a single member. Until now the hot-air treatment has been applied at Bellevue by means of a simple thermostat manufactured on the premises. By this means only a comparatively low temperature could be secured. The hot-air treatment is a modification of the Turkish bath, the great advantage of the former being the non-respiration of the heated air by the patient and the consequent possibility of securing a much higher temperature. The present apparatus permits the patient's head to be uncovered and also allows of frequent moist applications to the forehead.

PHILADELPHIA.

Bequests.—By the wills of Mrs. Rebecca Emslie and Mr. George W. Miles, which have lately been filed, over $130,000 has been left to the various hospitals and charitable institutions of the city.

Home for Incurables.—The J. Lewis Crozer Home for Incurables at Chester has recently been dedicated. The building has accommodations for 160 patients. Dr. D. P. Maddox has been appointed chief surgeon.

Episcopal Hospital.—A new nurses' home, four stories in height, has lately been added to the hospital facilities. The building contains more than 80 rooms.

Tuberculosis Meeting.—The annual meeting of the Pennsylvania Society for the Prevention of Tuberculosis was held April 11, 1900, at the Academy of Natural Sciences, Philadelphia. Dr. Guy Hinsdale was elected president and Dr. Alexander H. Davisson secretary.

Health Report.—Deaths in the city for the week ending April 21st were 739, an increase of 48 over the previous week and 234 over the corresponding week of last year. Contagious diseases: Diphtheria, 71 cases, 15 deaths; scarlet fever, 62 cases, 10 deaths; typhoid fever, 77 cases, 14 deaths. There were 31 deaths from influenza.

Physician's Life Threatened.—Dr. Charles Shaffner narrowly escaped injury at the hands of an insane woman last week. Five shots from a revolver were fired at him, but luckily none of them took effect. The woman appears to have been plotting the deed for some months, testifying that voices from Heaven had commanded this action.

College of Physicians.—The Section on Gynecology met April 19th. Dr. C. P. Noble reported two cases of epithelioma of the vulva. He has had but four cases, three of which have died. The fourth, a woman aged sixty-three years, has now lived nearly two years after operation with no signs of recurrence. If the case is seen early enough for operation he advises wide excision of the parts and a dissection of the chain of lymphatics, and their including fatty tissue, which leads up to the groin as well as the glands of the groin itself.

Dr. M. O'Hara, Jr., demonstrated an anastomosis forceps which is exceedingly simple in its construction and working. The instrument consists of two pairs of long-bladed forceps which can be fastened together by a serre-fine clamp. The forceps are applied one on each side of the portion of intestine to be resected, the resection made, the forceps approximated and fastened together, and the ends of the intestine united, preferably by mattress sutures. The advantages claimed are: The rapidity and ease with which an anastomosis can be done; the lessened risk of after contraction; the cavity of the bowel is not exposed at any stage of the operation, thus limiting the risk of infection.

Dr. R. G. Le Conte reported two cases. One was the removal of a multilocular ovarian cyst weighing 32 pounds, six weeks after the patient had passed through normal labor. The second case was one of traumatic rupture of a dermoid cyst. The patient had suffered from pain in the back and abdomen for a period of four years. After a severe fall upon the right side of the abdomen, increased pain was felt and bloody urine was passed. A fibroid mass was felt at the right side of the vagina. Abdominal section revealed the presence of an oily fluid in the peritoneal cavity and a greatly thickened omentum. Matted hair, part of a jaw-bone, teeth, etc., were found. The sac of the cyst was adherent to the ovaries, uterus and rectum.

CHICAGO.

Presbyterian Hospital Fund.—The Easter offerings of eighty churches of the Chicago Presbytery were devoted to this fund. Nearly the whole of the amount desired, $20,000, was raised. The greater part of this sum will go toward the expenses of electric lighting and a sterilizing plant.

Vital Statistics.—During the week ended April 14th there were 558 deaths reported in this city, this being 14 fewer than the preceding week, and 21 fewer than during the same week of 1899. It is noted, in comparing the past week with the corresponding period of 1899, that fewer children but many more aged persons are dying this year. The mortality of those under 5 years of age amounted to 134 last week, while one year ago 200 died at this age, a decrease of 66 for the week. During the past week the mortality of those over 60 years of age was 142, as against

115 for the corresponding week of 1899, or an increase of 27 for the week just ended. Pneumonia continues to be the principal cause of death, there having been 127 cases recorded during the week. Deaths from influenza numbered 27 during the week, the largest number from this cause for any week this year. There was only one death from scarlet fever, the lowest on record since the week ended Jan. 1, 1899.

Out of the 4138 pupils examined during the week, 251 children were excluded.

Quinine as an Oxytocic.—At the meeting of the Chicago Medical Society, held April 18th, Dr. Gustav Kolischer presented notes on some points in obstetrical practice. Attention was especially called to the diagnosis, treatment and position of the mother in cases of anterior vertex presentation, as the pelvis is in this condition frequently malformed, giving rise to serious complications. According to statistics, this condition is met with in from 8 to 10 per cent. of all confinements. The author believes in the effectiveness of quinine, which does not produce nor increase the pains, as is believed by so many, but, on the contrary, is extremely effective in regulating the pains and making them less exhaustive to the patient.

GENERAL.

Fate of the Hospital Ship "Missouri."—The board of officers from Washington who have been inspecting the hospital ship "Missouri," have recommended that she be turned over to the Quartermaster's Department for use as a freight ship.

Folding Bed Fatal.—Dr. A. B. Allyn, a prominent physician of Chadron, Ohio, has died of injuries received recently by being shut up in a folding bed.

Canned Meat for Soldiers.—War Department officials have been compelled to resort to the use of canned roast beef for subsistence of the army in the Philippines. This is due to the fact that it is absolutely essential that the soldiers shall be served with fresh meat and because of the impossibility of providing refrigerated beef or cattle on the hoof under existing conditions.

Abuse of Red Cross Privileges.—A dispatch from Pretoria announces that when the so-called ambulance corps recruited in Chicago for service with the Boer Army reached the Transvaal capital, half the members of the organization immediately enlisted, and, tearing off their Red Cross badges, accepted the Mauser rifles provided for them by the pious burghers. Consul Hay immediately expressed his disapproval of this episode to the Boer Government and informed it that he would report its details to his superiors in Washington. Such action on his part was eminently proper, and it is to be hoped that it will lead to the taking of effective precautions against any further abuse of Red Cross privileges. The Red Cross will find its future work seriously hampered if it permits men wearing its symbols to violate their pledges of neutrality, and to use its immunities as a means of aiding one belligerent against another.

Roentgen again Honored.—The National Academy of Science, at its recent session in Washton, D. C., awarded to Wilhelm Conrad Roentgen, the inventor of the X-ray, the Bernard medal. This medal is presented only once in five years, and is given to the person making the most important scientific discovery during that period.

Women Doctors Wanted in China.—Mrs. Wellington White, a missionary doctor from China, made an impassioned address at one of the meetings of the Ecumenical Conference now in session in New York, and a fervent appeal for more women doctors in China. "Twenty years ago," she said, "when I went into the Province of Kwang-Tung, there were 40,000,000 people there, of which 20,000,000 were women, and not a woman doctor among them all, and the men would rather let their wives die than allow a man to cross the threshold to treat them.

Examination for the Marine Hospital Service.—A board of examiners will be convened at the Service Building, 378 Washington Street, New York City, Wednesday, May 23, 1900, for the purpose of examining candidates for admission to the grade of assistant surgeon in the United States Marine Hospital Service. Candidates must be between 21 and 30 years of age, graduates of a reputable college, and must furnish testimonials from responsible persons as to character. For further information, or for invitation to appear before the Board of Examiners, address Supervising Surgeon-General, United States Marine Hospital Service, Washington, D. C.

The Plague.—The reports from Honolulu, April 17, *via* San Francisco, announce that only one case of plague has appeared since the previous report, that of a half-caste girl, aged thirteen years, ending fatally. The cities Hilo and Kahului are pronounced clean of the disease. The steamer "Australia" was the first since the outbreak to leave Honolulu carrying steerage passengers for San Francisco. The vessel sailed April 17th. The sudden deaths of Filipinos and Chinamen in the Central Market at Manila have led to an investigation showing that fifteen cases of the plague, fourteen of which were fatal, have occurred within a week. The market is located in the center of the city. In black, rotten, wooden buildings, the keepers of the stalls live, with their families huddled together in great filth. Some of the victims were stricken and died within an hour. There have been several deaths in other sections of the city also which have been traced to infection from the market. Recently, after all the market people had gathered, the health officers threw a guard around the buildings, and will keep the inmates quarantined there for a fortnight. They will then burn the market. The total number of bubonic plague deaths thus far are 119 Chinamen and 66 Filipinos.

Last week we reported the appearance of the

plague at Aden; since that time there have been cases reported at several points on the Red Sea. Considerable alarm is expressed in Australia lest the bubonic plague be spread by the rabbits, and a commission has been appointed to investigate the possibility of rabbits, like rats, carrying the dread disease. A report that rabbits had introduced the plague into Northern Victoria caused a panic in that colony. Throughout India, during the week ending April 18th, the number of fatal cases of plague slightly decreased, but the aggregate was upward of 4,000. The famine continues a source of great distress. One district lost 1,000,000 cattle out of 1,300,000 head and almost numberless human beings were found dead from starvation. In addition, children were found wandering in all directions, homeless, naked, and emaciated, and cases were reported of children being sold. The official reports fully confirm the worst stories of the terrible nature of the distress. It is also announced that the natives are developing ugly feelings and are attacking Europeans. A great crowd of natives murderously attacked a party of soldiers at Shahpur, the military center of the Northwest provinces. The soldiers were rescued with difficulty and in an unconscious condition. The Viceroy of India, Lord Curzon, wires that the recent rainstorms have not improved the situation, that the demands for relief are increasing, now reaching 5,319,000 persons, but that the arrangements for relief are equal to the increasing strain. Over 5,000 bushels of corn will be shipped from the State of Kansas to the famine sufferers of India. The United States Navy Department has secured a five-thousand ton steamer to carry the food supplies collected in New York by charitable institutions to these plague and famine-stricken sufferers. A steamer has also been secured at San Francisco to carry similar supplies from that port.

Divine Healer's Mail Held.—Twelve sacks of mail addressed to Francis Truth, the "divine healer," who was arrested recently at Boston, charged with fraud, have been impounded by the United States Government under the usual "fraud order." Many of the thousands of letters contained in the sacks carry money for "absent treatment." Truth's usual charge was $5 for absent treatment, so that necessarily the amount of money contained in the letters is very large. The twelve sacks of mail will be opened by the postal authorities. The letters which bear names and addresses on the envelopes will be returned with the money contained therein to the writers. The other letters will be sent to the Dead Letter Offices at Washington to be opened.

The "Maine" Reaches England.—The United States hospital ship "Maine" arrived at Southampton April 23 from South Africa. Mesdames Adair, Ronalds, Blow, and others of the Hospital Ship "Maine" Fund Executive Committee, with Mr. Baker, President of the Atlantic Transport Company, intended to give a cordial and elaborate reception to the "Maine" and Lady Randolph Churchill. A special steamer had been secured to take the party to the Solent to meet the "Maine" and escort her to the docks. But, to the chagrin of all, the hospital ship's early arrival frustrated the plans, and the committee, on reaching Southampton, found the "Maine" already berthed at her quay. She brought altogether 151 men and 12 officers. Fifty of these were surgical cases. The enteric fever patients made wonderful recoveries under the American cold-bath treatment. There were three deaths during the voyage.

Dr. Schenk Coming.—If there be any truth in a rumor widely prevalent, America is again to pay the penalty of her boast to be "a refuge for the oppressed of every nation," as Dr. Schenk, of "Determination of Sex" fame, is said to be about to betake himself to our shores. It will be remembered that he was compelled to resign his chair in the University of Vienna, on account of his famous brochure, some months ago.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, April 21, 1900.

DIVISION OF PROFESSIONAL OPINION UPON MIDWIVES' BILL—THE ALLEGED ARISTOCRACY OF THE PROFESSION—REELECTION OF DR. CHURCH AS PRESIDENT OF THE COLLEGE OF PHYSICIANS—TELEGRAM TO THE PRINCE OF WALES—CESSPOOL UNDER RESTAURANTS IN LONDON—EXAMINATION OF MILK COWS IN LONDON—SATURDAY HOSPITAL FUND NOT SHRINKING—SIR WILLIAM PRIESTLY.

The wide divergence which exists between the two great classes of English medical men, the consultants and the general practitioners, has seldom been more clearly and in some respects amusingly illustrated than in their attitude upon the proposed Midwifery Bill. The views of the former class are well typified in the editorial remarks of one of them in the *Practitioner*. These begin with the astonishing statement that many practitioners would be glad to turn over all their confinement cases to competent women, and that the majority would prefer to leave the cheaper class of midwifery in their hands! Than which a better illustration of utter and complete "detachedness" from the feelings and needs of the lowly family physician could hardly be imagined. Think of the possibility of holding family practice without attending labor cases, to say nothing of even the "cheaper class" of these, as indispensable sources of income.

In his further admonition to the mass of the profession that legislation of some sort is inevitable and that they will gain nothing and lose much by letting the impression get abroad that their opposition to it is merely a dog-in-the-manger fight to retain a paying monopoly, there is

probably more truth, although it is hardly to be expected that the struggling country doctor will relish hearing it from the serene heights of Brook Street or Cavendish Square.

On the other hand, the practitioners, both through their editorial mouthpieces and by public meetings, are denouncing the bill as "calamitous," reproaching the General Medical Council and the College of Physicians and Surgeons for their lukewarmness in opposing and for even partially consenting to its passage. Their demand that the new licentiates should be termed "midwifery nurses" and permitted to practice only under the direction of a physician, does perhaps smack a little of selfishness and is certainly injudicious as insisting upon the unattainable, although it would redound to both the health and happiness of the community if it could win.

All this is simply typical of the friction which is continually cropping out between the two divisions, the officers and the privates, so to speak, of the medical army. The consultants have, not unnaturally, secured a heavy preponderance upon the great governing bodies and councils of the profession and as most of them have not been in general practice for years and some of them never in family practice at all, there is a continued cry going up from the rank and file of the profession for more direct representation upon these bodies and more sympathetic and intelligent action upon the questions of vital importance to the practitioner.

Even at the recent annual meeting of the Polyclinic, the question came up in the shape of a vigorous demand for larger representation upon the Council, whose twenty members it was alleged included only one actively and three nominally engaged in practice.

Dr. William Selby Church has been reëlected president of the Royal College of Physicians in accordance with the unwritten law of that body in regard to second terms. The death-roll of the year was read by the President, and included such well-known names as Sir William Roberts, Sir Richard Thorne-Thorne, and the Reverend William Hicks (Bishop of Blomfontein). This, with the statement that the finances of the College are in a far from satisfactory state, gave rather a gloomy cast to the proceedings, but this was lightened somewhat toward the close by the ancient custom of carrying round a silver bowl filled with new silver coins (half-crowns) in small envelopes in payment of the attendance-fee of the members, and also by the, to transatlantic eyes, almost farcical announcement that a special telegram had been sent to the Prince of Wales congratulating him on his escape from assassination, His Royal Highness having recently been elected an Honorary Fellow of the College for some heaven-born reason.

The old and the established, no matter what its demerits, dies hard in England. It is reported upon apparently good authority that even today in London, the model sanitary city of the world in many respects, there are still houses whose sewage is conducted into cesspools dug out of the soil directly beneath them. One or two prominent restaurants in the "City," the central business part of London, are said to be in this predicament and the effect of the emanations upon the health of their employees is said to be most noticeable. The effect upon the customers could be but slight in any case, but what of the food and cooking utensils kept over night in such places? The average cellar-restaurant or hotel kitchen is often a gruesome place at best without any sewage-fumes as an addition to its charms. The charge ought certainly to be rigorously investigated.

It is gratifying to note that the report of the Saturday Hospital Fund for 1899, just issued, shows, in spite of the enormous claims of the war, an increase of nearly $5000 over the total for 1898, the entire sum being a little more than $100,000. Still better, the abandonment of personal street-collecting for the Fund, which was coming to be regarded almost in the light of an annoyance, has not resulted in anything more than a most trifling diminution of the amount collected, hardly $600 as between this year and the last one of the active collections.

The death of Sir William Priestly removes from the stage a figure whose prominence may be said to have been even greater outside of the profession than within its circle. Born of a family whose name stands high in the annals of science, a great-nephew of the famous discoverer of oxygen, of commanding presence and winning address, he had every natural endowment for success. And his success was largely of a personal rather than a purely scientific or literary character. The actual amount of his contributions to medical literature or progress was small in proportion to his prominence alike in practice, in Parliament, and in social circles. For years he had one of the largest and most fashionable consulting obstetrical practices in London, royalty itself being included in his clientele, which left him little leisure for writing or original research. He was, however, a prominent member of the staff of Kings College as consulting physician and professor of midwifery, and examiner in midwifery to the Royal College of Physicians and to the University of Cambridge and President of the Obstetrical Society, so that his activity in what might be termed the executive duties of the profession was great.

By a curious parallelism with Lord Lister, although born in England, he won his first reputation in Edinburgh where he was for three years in close association with Sir James G. Simpson, to whose tireless friendship and powerful influence much of his earlier success was due. It was largely upon his recommendation and vigorous championship that the young obstetrician was elected to the vacant chair of obstetrics in Kings College, shortly after he came to London, over the heads of two junior assistants and graduates of the College, who, by the sacred unwritten law of the London schools, considered

that the only choice of a candidate lay between them as Kings men. The skill with which Priestly soothed the irritation and outraged sense of propriety due to the "profanity" of his election, was a high tribute to his tact and gifts as a judge of human nature and manager of men, to which, indeed, his permanent success in practice was chiefly due, while his cleverness and fluency as a lecturer justified his appointment, so that he soon became personally popular with his colleagues, and on his resignation of the chair after only three or four years' occupancy, due in part to a severe attack of diphtheria and its sequelæ, he was unanimously elected consulting physician to the Hospital.

Although a Conservative all his life he was knighted upon the recommendation of Mr. Gladstone in 1893, and three years later was elected to Parliament as the representative of the Universities of St. Andrews and Edinburgh, one of the "blue ribbons" of scientific and literary fame in England. His work in the House was not of a prominent or highly public character, but his influence upon legislation, particularly that pertaining to the promotion of the public health was most useful and the profession was well represented by him. His death leaves a vacancy in Parliament which will probably be filled by another medical man, and Sir James Crichton Browne is prominently mentioned for the position.

TRANSACTIONS OF FOREIGN SOCIETIES.

COMPULSORY NOTIFICATION OF PNEUMONIA AND BRONCHOPNEUMONIA — ACTINOMYCOSIS DURING THE PAST TWO YEARS—MOSQUITO-THEORY OF MALARIA NOT YET SETTLED—CHEYNE-STOKES RESPIRATION DURING SLEEP AS A SIGN OF COMMENCING CEREBRAL ENDARTERITIS.

At the Academy of Medicine, March 20th, Grancher urged that pneumonia and bronchopneumonia should be placed on the list of diseases of which notification is compulsory, because they are diseases which are always contagious whether occurring at the time of an epidemic or at other times. In case of these two diseases, and in case of tuberculosis, disinfection can render the greatest service, because the agent by which they are transmitted preserves its virulence for a long time and is relatively easily destroyed by boiling or by chemical means. With measles, for example, the reverse is true. It is only contagious during the period of invasion and ceases to be so when the eruption is well out. Hence disinfection is practically useless in cases of measles unless complicated by bronchopneumonia, while it would be of the greatest value in pneumonia, bronchopneumonia and tuberculosis.

Vallin said that in the present state of science one is not justified in asking compulsory notification for pneumonia and bronchopneumonia, unless an epidemic occurs or a form of these diseases which is markedly contagious—the virulence of the pneumococcus being exalted, as it were.

Lereboulet objected to compulsory notification because one rarely sees instances in which disinfection would have prevented an attack of pneumonia, and also because many towns are without the means of proper disinfection.

After further discussion, April 3d, the Academy adopted the following resolution: "The Academy is of the opinion that the time has come to place *infectious* pneumonia and bronchopneumonia on the list of diseases of which notification is compulsory."

Poncet spoke at the meeting held March 27th of the cases of actinomycosis which were on record as occurring in France during the past two years. One should not make the mistake of relying upon the microscope for a diagnosis of this disease. The true diagnosis is a clinical one. The following symptoms are characteristic: A hybrid aspect, suggesting at once neoplastic and inflammatory lesions; slow and capricious growth, with cicatrization of old fistulæ in the immediate neighborhood of recent or extending lesions. Particularly on the face and neck, a diffuse induration, usually very painful, and muscular rigidity as soon as the superficial muscular planes are involved, and the absence of lymphatic enlargement, even although there are numerous sinuses and ulcers, are distinguishing characteristics. Of 26 cases reported, the disease occurred 21 times in the face and neck; twice in the cecal region, and once each at the umbilicus, anus, and in the pleural cavity. Inoculation invariably from an ear of wheat or the débris of cereals, almost always took place through the digestive tract. The progress of the disease was slow—3 months to 6 years—and often the parasites could not be found by microscopic examination until sought for many times. The termination of the disease was 15 times mentioned. Five patients died, 8 were well at the time of report, and 2 had suffered relapse. Surgical intervention did not appear indispensable. It should be confined to a simple incision, with scraping or cauterizing the sinuses. Iodide should be given internally. Eucalyptus has been recently highly praised, but Poncet said that he had not seen it accomplish any good result.

Laveran discussed the mosquito-theory of malaria, which he said was in harmony with many of the facts but not all of them, and to which there are some objections. For example, malaria is unknown in certain regions where mosquitoes flourish, while it occurs in some places where there are no mosquitoes. Observers are not agreed as to the method by which the mosquito transmits the parasite. If some experimenters have succeeded in producing malaria by the bite of a mosquito which had previously sucked blood from a malarial patient, a far greater number of such experiments have failed. The public should be impressed with the idea

that the larvæ develop in stagnant water and that any unnecessary stagnant water should be drained off, and the mosquitoes in the remainder should be killed by coal-oil or tar poured upon the surface of the water.

At the Medical Society of the Hospitals, March 16th, Rabe spoke of the occurrence of Cheyne-Stokes' respiration during sleep in a patient whose kidneys acted normally during life and were shown to be sound at autopsy. The Cheyne-Stokes respiration was due to cerebral arteriosclerosis, combined with cardiac asthenia; and when it occurs under such circumstances it may safely be regarded as diagnostic of commencing arteriosclerosis.

SOCIETY PROCEEDINGS.

THE NEW YORK COUNTY MEDICAL SOCIETY.

Stated Meeting, Held Monday, March 26, 1900.

The President, George B. Fowler, M.D., in the Chair.

Dr. Clarence C. Rice read a paper on "Some of the Reasons Why the Surgical Treatment of Nasal Disease Has Been Placed upon a Conservative Basis." (See p. 641.)

Therapeutic Cycles in Laryngology.—In the discussion Dr. Beverley Robinson said that just as there are cycles in the therapeutics of most diseases, so there have been in the treatment of nasal affections. Twenty years ago Dr. Robinson insisted that the diathesis underlying certain manifestations in the nose was frequently much more important and needed treatment rather than the nasal disease itself. The constitutional condition of the patient, he urged, was the cause of the nasal symptoms and it was only by improving this that any permanent relief could be obtained. Although many changes have come in rhinology during the last twenty years, there seems no reason to change this opinion except, if possible, to emphasize it more strongly than ever. There is undoubtedly more danger in operations upon the nose than has been thought. Not only is there a certain amount of immediate danger, as reported deaths show, but there is a large risk of serious after-results from useless operations. Pathways for the entrance of germs are frequently provided by the mutilating effects of operations, and the physiological function of the nose as the gateway of the respiratory tract is often so interfered with that pulmonary affections become much more frequent than before. There is still a limited field for surgery in the nose, but it must be remembered that many of the operations done so thoughtlessly are of considerable moment and demand for their proper accomplishment a previous surgical training. The entrance of a number of men into laryngology and rhinology without previous surgical training has undoubtedly hurt the surgical side of the specialty. The first principle of all medical treatment *non nocere* has only too often been flagrantly violated. Many a patient could have endured much better the nasal condition from which he was suffering than he can the results of operation that was supposed to relieve his symptoms. An occasional feeling of fulness in the nose is a good deal easier to bear that the scabs and constant dryness, with consequent discomfort, which will exist in the nose so persistently as the result of mutilating operations upon the nasal mucous membrane.

Specialist and Family Physician.—Dr. Robinson hopes to live long enough to see the time when the general practitioner will control the specialist and not only counsel his being called in consultation, but say how far he shall go in the application of his special therapeutic measures to the patient for whom he is called. As it is now, the practitioner among the better classes is little better than a soup-ladle, dishing out patients from his family practice for the various specialists. This is undignified and the time will come, and that before very long, when the family practitioner will resume all his old-time importance and then the mistakes that specialists continually make in carrying their fads too far will no longer be possible.

Dr. W. C. Phillips said that a little knowledge is a dangerous thing in any branch of medicine and that it has been particularly hurtful in rhinology. Specialists ready-made in a few weeks have considered that they were capable of judging of nasal conditions without reference to other parts of the body and mistakes have necessarily followed. Experienced workers in the nose have long since agreed that swollen turbinate bodies or a congested septum are not necessarily surgical conditions, but are often only symptoms of affections in other parts of the body. The local treatment of them will necessarily be unsuccessful in the end, although it may seem to give temporary relief. The only rational treatment is the therapeusis of the cause of the symptoms in the organs that are primarily affected. No specialist can hope to succeed unless he has been a general practitioner for a long time.

Constitutional Treatment.—Patients are often better freed from respiratory difficulties by a calomel purge than by any local measures, however well planned these may seem to be. Fortunately, patients are beginning to understand that symptoms in the nose do not always indicate direct local treatment. It was the custom to have patients come to the rhinologist with the remark that they wanted to have their noses bored out. This expression is no longer heard as frequently as it used to be, and the fact points to a very sensible change in the opinions of the laity with regard to nasal symptoms. The most important constitutional faults that give nasal symptoms are rheumatism, gout, and the uric acid diathesis. The most potent cause of nasal disturbance in general is digestive trouble.

Prompt relief of many a congestion and even of a certain amount of hypertrophy is frequently obtained by treatment of the digestive symptoms.

Direct Causes of Nasal Symptoms.—Dr. Rice's suggestion as to the influence of the use of alcohol and tobacco in excess as frequent causes of nasal symptoms is a most important and timely one. They are undoubtedly the cause of many conditions that have usually been attributed to quite other etiological factors. Cold in the head, that scapegoat for most acute nasal conditions, is usually not due to exposure to drafts. Patients who are the most careful with regard to exposure to cold acquire exacerbations of their nasal disturbance for very slight reasons. It is evident that other factors besides mere exposure to cold enter into the etiology of these nasal disturbances. The auxiliary causes usually belong to the realm of bacteriology, and it is here that we must look for the cause of acute rhinitis and pharyngitis which often leave their marks upon the nasal mucous membrane in the shape of chronic changes. Overwork and fatigue from overexertion frequently disturb the circulation and set up certain trophic nerve influences that become prominent causes in the production of nasal symptoms.

Field for Operation.—Dr. Robinson said that a number of young rhinologists would surely find in his nose indications for operating and some of them had even suggested it. This is not an unusual experience among rhinologists and it emphasizes the necessity for more conservatism in suggesting operations. There is a distinct field for operative surgery. Conservatism is not the only watchword. To treat nasal conditions without operative interference is surely to lose the great benefit that can be derived from surgery under appropriate circumstances. Nasal surgery requires, however, experience, skill, and training, just as does surgery in other parts of the body. If the speciality of the nasal surgeon is looked at in this way there is a great field for his labors.

Diathesis.—Dr. Quinlan said that the causes of nasal and laryngeal disease, if considered rationally, lead one far beyond what can be seen in the nasal speculum or the laryngeal mirror. In the talk about diathesis this evening the most important constitutional conditions that come under this head, namely, syphilis and tuberculosis, have been omitted. Constitutional conditions always influence and very often are the sole cause of nasal symptoms. It is not an unusual thing to have a parent bring back a child dissatisfied after the operation for adenoids. The apathetic expression, the mouth-breathing, the tendency to open mouth with its foolish look, something of the nasal speech, and other symptoms that it was promised would be cured by the operation still remain. The cause that led to the adenoids originally has not been eliminated and the symptoms that were made more marked by the presence of the pharyngeal tumors do not entirely disappear after removal of the latter.

The importance of water without and water within is becoming ever clearer in our modern life and must especially not be forgotten by the nasal specialist. In our dry superheated rooms conditions of the nasal mucous membrane develop that do not require special treatment, but demand more moisture in the air we breathe. Air and exercise are potent factors for the relief of nasal symptoms. A cold bath will often relieve rhinitis by causing a diversion of the blood supply into the cutaneous capillaries. It must be remembered that the turbinal tissue in the nose acts as the vestibule of the lungs to keep out impure and irritating air. Its function must not be hindered. If this great filter of the respiratory system is removed not only nasal symptoms will be much more prominent, but also the tendencies to pulmonary disease will be much increased. Conservatism must be the watchword of the operating laryngologist. It has taken a good many years to reach this standpoint. Now the lesson must not be lost. "Knowledge comes, but wisdom lingers."

Excessive Smoking.—Dr. Emil Meyer said that while excessive smoking undoubtedly does harm, the objection to the use of tobacco may become a fetish. Atrophic conditions of the nasal and pharyngeal mucous membrances occur also in females and in that class of females who do not smoke. In the same way alcohol is undoubtedly a serious factor in certain laryngeal conditions and yet the taking of moderate amounts may do no harm. There are extremes in the condemnation of alcohol and tobacco to which laryngologists should not go.

The electric cautery can never be condemned enough. The inventor of electric cauterization methods for the nose has undoubtedly a great deal to answer for. A distinguished specialist in rhinology said not long ago that the main part of his time was occupied in breaking down the synechiæ of the nasal mucous membrane that had been left by electric cautery in the hands of the would-be rhinologist and the general practitioner. The galvanocautery certainly has a very limited place in the therapeutics of nasal diseases. The operative field for the specialist in rhinology must concern especially the treatment of the accessory sinuses of the nose. These the general practitioner can scarcely be expected to touch. He may put his patient into good general condition in order to be sure that the nasal symptoms will not disappear when this is done, and then, if there are symptoms that seem to implicate nasal sinuses, he should send his patient to a reliable specialist. For the specialist, under these circumstances, the best advice is Davy Crockett's maxim, "Be sure you're right, then go ahead."

Surgical Technic.—Much more consistent results in the field of nasal surgery will uniformly be obtained if careful precautions are taken to secure as far as possible an aseptic field for operation and the most thorough surgical care during and after the operation. It seems a good deal to

demand an assistant and a nurse for a simple adenoid operation. It looks like needless expense, but, after an experience of years with never a septic result with such accessories, Dr. Meyer is thoroughly convinced that the additional help is well worth the while. Dr. Goodwillie said that respiration is more important than food. If respiration is to be properly continued the mucous membrane must function normally. Mucous secretion must have a chance to get out, otherwise irritative conditions will surely develop. Dr. Goodwillie has, then, the very greatest respect for this important tissue. He saves all of it that is possible and hesitates as much to remove a bit of it as he would to remove any portion of visible tissue whose loss would be noticeable. Serious mistakes have been made in the past in removing this mucous membrane. Its removal is always followed by serious results. A good deal of bad surgery has been done in the nose during the development of modern rhinology. Adenoids must be removed, but only the hypertrophied granular tissue and not an indefinite amount of mucous membrane lying all around them. If other tissue is removed, harm will always be done. There have even been cases in which lasting injury has been done to the pillars of the fauces during an adenoid operation.

Local and Constitutional Treatment.—Dr. Rice in closing the discussion said that it must be remembered that it may be necessary to remove an occlusion of the nose, even if it should come from the liver or the lungs or from some digestive disturbance. This is especially true where the ear is interfered with. Constitutional treatment may be so slow in its action that important structures will be damaged before we are able to prevent by this means the development of lasting pathologic lesions in them. A great step in advance has certainly been made in rhinology in recent years inasmuch as we have done away with the use of nitrate of silver, zinc and copper solutions, which used to produce serious irritation of the nasal mucous membrane. When catarrhal conditions exist along the digestive tract the rhinologist can be of the greatest service to the general practitioner by relieving the catarrhal conditions of the upper part of the mucous tract. Disturbances of secretion in these parts react to produce reflex pathologic conditions in the stomach and other parts of the digestive tract.

Requisites of the General Practitioner.—Dr. August Caillé said that while the family practitioner used to be the all-important member of the medical profession he has now lost most of his prestige. The fact is that no one mind can contain all medicine and the all-round medical man is swamped by the amount of new material which is constantly accumulating on all sides in the realm of medicine. Even the specialist finds it hard to keep up in his own branch. If he knows but one language the difficulty is great enough; if he can read several then he realizes the futility of trying to absorb everything. The general practitioner has now become, in wealthy families at least, little more than the master of ceremonies in the direction of the health of the household. He diagnosticates in general the condition that exists and directs what specialist shall be applied to for treatment. The details of the treatment are carried out by a trained nurse. Medicine seems to many a field for the gaining of a good and easy livelihood. As a matter of fact, in recent years the profession has become overstocked. This has precisely the same effect as does an overstocked market. There is a drop in the prices to be paid and this will cause an inevitable diminution in the supply. There is not room enough for all who enter medicine. In the midst of this overstocking of the medical market there comes up this important question: Is there a place for the general practitioner or is his genus doomed to extinction? There are two reasons why the general practitioner, as such, will not disappear from the field of competition in medicine.

Future of the General Practitioner.—The two reasons why the general practitioner will live on is, first, that many people refuse to give him up. And, secondly, the public has come to realize during recent years the danger of immature specialism, and has taken to heart the important lesson that a large amount of the specialist's operative work is harmful or at least ill-advised. The family practitioner will save these mistakes by his good advice and so preserve his *clientele* from specialistic fads. The general practitioner may elect to develop for himself certain features of his work. He may, as it were, specialize, first, on physical diagnosis, second, on laboratory methods, third, on regional diagnosis, fourth, on dietetics, hygiene, hydrotherapy and physical methods of therapeutics, or fifth, on minor surgery. It is Dr. Caillé's opinion that he should not handle obstetrics. In the matter of physical diagnosis he should study especially the possibilities of information that may be gained from the careful examination of the various orifices of the body. He may not, perhaps, be expected to use successfully the opthalmoscope or the cystoscope, but he certainly should be able to gain all ordinary information from the nose and throat and from the examination of the stomach-contents and from the use of specula. Patients cannot be expected to pay two fees for the diagnosis of conditions that involve no more special knowledge than these procedures. The diagnosis will certainly be expected of the general practitioner.

Obstetrics and General Practice.—There are two reasons why the general practitioner should not take obstetrical cases. First, they involve a considerable amount of night-work, and secondly, as general practice brings the practitioner in contact more or less with contagious diseases, this makes him a source of danger for the puerperal patient. The busy practitioner cannot do his patients justice if besides attempting day-work he stays up at night. His hysterical haste

is not paid for sufficiently and sins of omission inevitably ensue. The compensation that the practitioner would obtain for his obstetrical cases can be replaced by what he obtains for minor surgical practice. The simon pure medical practitioner has no place in future medicine. If a medical man objects to the use of the knife, his only hope is to drift into some bloodless specialty.

Practical Considerations.—A certain amount of laboratory work is very important for the general practitioner and will be even more so in the future. For this he no more needs a private laboratory than he needs a private livery-stable to keep his horse in. A great change will have to come over medical teaching in the very near future. An amount of valuable time during student-days is wasted in the study of valueless drugs that are still retained in the materia medica. The much more important theraputic measures, mechano-, hydro-, and dieto-therapeutics are unfortunately neglected. These mechanical and physical methods, with a few drugs, must constitute the armamentarium of the practical physician. In order to keep up with the progress of medicine, the practitioner must do post-graduate work. This is more necessary for the country practitioner than for the medical man who lives in the city and who is more in touch with the progress of medicine. For post-graduate laboratory work, Europe is still ahead of us. Practical clinical post-graduate work can be done better here in this country. All medical men should begin their careers as general practitioners. Dr. Caillé does not hesitate to predict that the general practitioner of the future will be especially a diagnostician, a sanitarian and a minor surgeon.

Few Successful Physicians.—Dr. Walker said in discussion that he had been informed by the dean of a prominent medical college that only one out of every five medical men who graduate succeeds in making a living exclusively from his profession. There is no doubt that the profession is being overcrowded. Dr. Caillé's opinion that the practioner of the future must devote his attention to minor surgery is a very suggestive thought. At least sixty per cent. of the ordinary young man's practice will come from this source

Dr. Edebohls said it is important that the general practitioner should assure himself that his patient needs a specialist's care before he sends him to the specialist. Only the other day a puerperal woman was referred to him for curettage and he found absolutely nothing the matter with the sexual organs, but did find an acute pericarditis. It would have been extremely sad to have attempted operation in this case for death on the table would almost certainly have resulted from the anesthetic.

Dr. Knopf said that there is undoubtedly a great waste of time in the study of useless drugs. Much more time should be devoted to hygiene and diet than at present. The general practioner should be able to detect incipient tuberculosis and treat it. For this he may have to examine the members of predisposed families every six months. The procedure would certainly be thoroughly justified if by it we were able to keep in abeyance the great white plague of the north.

NEW YORK ACADEMY OF MEDICINE.—SECTION ON LARYNGOLOGY AND RHINOLOGY.

Stated Meeting, Held Wednesday, March 28, 1900.

Wendell C. Phillips, M.D., Chairman.

Dr. Coakley presented an improved transillumination instrument. The instruments at present in use for this purpose are very hard to sterilize thoroughly. Dr. Coakley provides a glass tube that fits over the electric lamp and goes somewhat beyond it. It is this tube alone that comes in contact with the patient's mouth. It can easily be removed and thoroughly sterilized by boiling. This glass covering serves besides the very useful purpose of keeping the transilluminator cool enough to allow of its presence in the mouth for a considerable time. Glass itself is a poor conductor of heat and besides there is a non-conducting layer of air between the lamp and the outer glass tube, which further prevents any disagreeable heating of the outside of the instrument.

Dr. Levin presented a case of atrophic rhinitis at the age of twelve years. The patient has now been under his observation for some four years. The condition was well marked at the beginning of that time and has progressed but slightly. By careful cleansing the patient is kept reasonably comfortable, although otherwise the affection seems to yield very little to treatment.

The subject of the evening, the discussion of atrophic chronic rhinitis, was then taken up.

Etiology of Atrophic Rhinitis.—Dr. Frank H. Bosworth said that the opinions on this subject expressed in his paper at the Congress in London, some twenty years ago, remain still substantially unchanged. He there presented some specimens from the mucous membrane of cases of atrophic rhinitis, which had been obtained by the snare—a perfectly unjustifiable procedure, except for the scientific value of the observations made possible by it. At that time he expressed the opinion that chronic atrophic rhinitis is a development from purulent rhinitis of long duration. Before that the general opinion had been that atrophic rhinitis develops somewhat as does atrophic cirrhosis of the liver. It was considered that hypertrophic rhinitis is the primary stage. Only one case of such a progression has ever been recorded. If that is to be accepted it is unique in medical literature. Inflammatory conditions in the mucous membrane do not, as a rule, lead to the production of connective tissue, but only to an increase of secretion. In children the process is confined to the epithelial layer and

proliferation of the epithelial cells takes place so that the original mucous secretion becomes cloudy and almost purulent in character. The process then extends into the simple and compound follicles of the mucous membrane with a like involvement of their epithelial cells. A deposit of connective tissue then takes place around the follicles. Like all connective tissue this has a tendency after a time to contraction. After a year or two, sometimes three or four, of excessive secretion the secretory fluids become thick and inspissated. They form thick crusts and their contraction interferes by pressure with the blood-supply. Between the contractile connective tissue within the mucous membrane and the crusts on its surface the blood-supply to the turbinated bodies is very much interfered with. The mother of bone, the periosteum in this region suffers and the result is a failure of the turbinated body to develop properly.

Origin of Symptoms.—Theories almost without end have been very ingeniously constructed to explain the various symptoms of the disease. A special form of secretion has been suggested as the cause of the crusts, or a special form of bacillus that causes the mucous material to become inspissated. A number of theories have been advanced to explain the disagreeable odor also. To any one who uses common sense, however, this does not seem very hard to explain. Animal matter, that is, albuminous material of very unstable chemical equilibrium, is retained for twenty-four to forty-eight hours in the nose. It would be surprising, then, if it did not decompose and smell. Chronic atrophic rhinitis usually commences in childhood at five or six or seven. After five to six years of progress, crusts are formed and then the odor begins to be the most notable symptom. Amelioration of all the symptoms very frequently takes place at the age of forty, or shortly thereafter. Dr. Bosworth has seen but one case of fully-developed atrophic rhinitis chronica in a girl of twenty-one that was completely cured. The rhinologist is in a much better position, therapeutically considered, at present with regard to the disease, than he was some years ago. All of the symptoms can now be so controlled that the patient has comparatively little discomfort, while the annoying smell, so offensive to friends, can be so overcome as to be unnoticeable.

Recent Contributions to Etiology and Pathology.—Dr. Jonathan Wright discussed some of the recent theories brought forward by German authorities as to the etiology of chronic atrophic rhinitis. The subject has been approached from the standpoint of ethnology and craniology. It has been pointed out that it is especially the flat type of skull that is liable to be affected by this atrophic condition of the turbinate bones. The form of skull has a definite relation to the form of the nasal passages and this latter to the development of atrophic conditions. In Switzerland it has been noted that in 97 per cent. of patients ozena occurred in individuals who had more than the average width of face. In a word, fetid rhinitis occurs only in the broad-faced. It has also been noted that there is a congenital metaplasia of the epithelial cells of the nasal mucous membranes. Instead of cylindrical epithelium, which is normal to this part, squamous epithelium occurs as the result of congenital influences. Individuals so affected later develop atrophic rhinitis. This tendency to squamous epithelium within the nose occurs especially in the broad-faced type of skull, in which the more open nostrils and consequent exposure of the epithelium to the air lead to its taking on more the character of the neighboring skin surface. These observations on skull types and their influence on the development of atrophic rhinitis have been made so far only in Switzerland. As is well known that the brachycephalic type of skull prevails very generally in Switzerland. It would not be surprising, then, to find that a large proportion of people afflicted with any ailment there would be of the broad-faced type. It is doubtful if a corresponding series of observations made, for instance, in the Iberian Peninsula where the dolichocephalic type of skull prevails, might not give directly opposite result. Meantime this theory of the etiological connection between the type of skull and the development of atrophic rhinitis adds another and a very interesting phase to the discussion of the etiology of the affection. We have heard it said that atrophic rhinitis chronica develops from hypertrophic rhinitis, or from purulent rhinitis; that it occurs in people with high palates, or, according to others, in people with especially low palates. Bacteriology has put in her claim to explain the origin of the disease, and the pseudodiphtheria bacillus as an etiological factor had for a long time quite a vogue. Of late it has been claimed that the disease is originally a neuropathy, that is, an atrophic neurosis. Evidently it is not yet possible to decide what the etiology of the disease is. It is probable that most of the factors mentioned have some influence, while no one of them is the exclusive cause. It must be borne in mind in discussing the etiology of chronic atrophic rhinitis that the affection preponderates in women. At least 70 per cent. of the patients, according to a large number of statistics, are of this sex. It has been pointed out that women have not only actually, but relatively, a smaller nose than men. This has been taken to indicate that it is especially smallness of the nose which predisposes to the development of the affection. Hereditary syphilis has been claimed to play an important part in the causation of the disease. Fournier has now pointed out that, as the result of hereditary syphilis, not only do various deformities of the nose occur, but patients are apt to be born with a relatively smaller nose than is normal, though the organ may be perfectly regular. This question, however, needs further observation before any decision as to the value of this factor in the etiology of the disease can be made. One thing is certain, the bacteriological factors that a

few years ago were considered so prominent in the etiology of chronic atrophic rhinitis are now, in the words of a distinguished statesman, sinking into "innocuous desuetude."

Dr. Clarence C. Rice said that dry mucous membranes may exist for long periods and yet not be due to chronic atrophic rhinitis. All dryness of the mucous membranes of the nose used to be diagnosed as atrophic rhinitis. We now know that an absence of secretion may exist for years, while normal mucous membrane remains and no true atrophy develops. This absence of secretion is often due to general malnutrition. It is especially seen in dispensary practice, because poor patients are liable to be living under conditions of diet, overwork, absence of good air and sanitation that make profound malnutrition very frequent. Another form of dry rhinitis occurs without atrophy in fat, phlegmatic people, especially those who use alcohol to excess. It is very constantly found in mouth-breathers. This dry rhinitic condition may be cured by discontinuing the alcohol and reducing the weight of the patient.

Differential Diagnosis.—Functional collapse of the mucous membrane, with absence of secretion and an anemic appearance, occurs especially in young adults of the poorer class, whose general condition shows that they are not in the best of health. True atrophic rhinitis occurs especially in children of any class, rich or poor, and the patients are frequently in good general health. In functional collapse the typically-wide nostrils of true atrophic rhinitis do not exist. In atrophic rhinitis there is destruction of the turbinate bodies and the mucous membrane covering them looks thin and granular, and usually has crusts on it. The extremely fetid odor is a very characteristic symptom. In simple dry rhinitis the mucous membrane has an anemic look, but does not seem degenerate and, while the breath may be unpleasant from general disturbance of the digestive tract, it is not as offensive as in true ozena. The middle turbinate body is very often enlarged in atrophic rhinitis. This enlargement does not occur in functional collapse. The milder condition does not usually end in atrophy. No heroic treatment is needed for functional collapse of the nasal mucous membrane. As soon as the general health can be improved relief will be experienced from the symptoms noticed and the appearance of the nasal mucous membrane will alter for the better.

Hygienic and General Treatment.—Dr. Delavan read for Dr. Thomas R. French of Brooklyn a paper on this subject. Under the term hygiene Dr. French does not include the precautions necessary to avoid nasal affections due to occupation. For these very little can be done except a change of occupation. The main lesson to be learned in the hygiene of the nose is how to cleanse and how not to cleanse the nasal mucous membrane in chronic atrophic rhinitis. Rhinologists differ widely as to the etiology of the disease, but they are agreed that the indications are to cleanse the nostrils locally, to stimulate the mucous membrane and to destroy the odor. The modern syringe is apt to be very unclean, and while the best-intentioned efforts are being made for the cleansing of the nostrils, the condition of the syringe may render the attempt nugatory. Some time ago, at Dr. French's suggestion, Dr. Van Cott drew up into a nasal syringe, supposed to be ordinarily clean, some sterile bouillon and allowed it to remain for a few minutes. The bouillon was then allowed to stand for a time and some of it injected into the peritoneal cavity of a guinea-pig. The animal died in eighteen hours from septicemia. In the peritoneal fluid a short bacillus and a micrococcus were found. Syringes that are as liable to contamination as this should not be used. Dr. French has recently had made a syringe the plunger of which is made of asbestos. This can be thoroughly sterilized by holding it over an alcohol lamp for a few minutes. This makes the syringe much less liable to carry infective material than with the old form of plunger, which practically cannot be sterilized. Dr. French likes the spray as least as well as the douche under all circumstances, and he considers that there is less danger to the ear from the use of the former. All atomizers should be boiled before use even when they are presumably new. Frequently atomizers are used once by a patient and then returned to a drug store to be exchanged. There is no guarantee, then, that because the atomizer is direct from the druggist's it may not be infected with micro-organisms. Strong antiseptics should not be used in the nose, and alkaline solutions are better borne than neutral or acid ones. For the dry feeling which causes so much discomfort, some oily solution should be used. This is only palliative in its effects and should be used intermittently. Its constant employment will lead to the nasal mucous membrane giving up entirely its function and will eventually make the condition worse.

The use of antitoxin for chronic atrophic rhinitis had many strong advocates not long ago, but they are constantly dropping out. Where tuberculosis exists, care should be taken to treat the patient for this condition and improve the general health as much as possible. Anemia or any dyscrasia should be appropriately treated. A change of climate commonly does good, notwithstanding the fact that a moist atmosphere is usually the most comfortable for the patient, the seashore is not always the best place for him. Quinine, iron and strychnine should be used freely where the general health is impaired. Inunction with oil often seems to be an excellent method of improving the general health where there has been considerable loss of weight. With regard to the underclothing, the use of linen mesh seems advisable. This underwear prevents to a great extent the tendency to take cold, often so noticeable in these cases. There still remain many defects in our treatment of chronic atrophic rhinitis, but we can control the fetid secretions almost entirely now and so make pa-

tients much more comfortable than they used to be.

Electrical and Mechanical Treatment.—Dr. Bryson Delavan said that mechanical treatment consists in the use of tampons, plugs, bougies and the curette. Gottstein's suggestion of the use of non-absorbent cotton was undoubtedly a step in advance in the treatment of chronic atrophic rhinitis. Certain drugs may be employed with advantage on the tampon and the medicated material gives better satisfaction than the plain. The use of the curette is justified where areas of hypertrophy of the mucous membrane exist besides the atrophic condition. The hypertrophic patches are apt to occur especially at the upper part of the septum. The galvanocautery may be used for the same purpose as the curette; for any other purpose it is sure to do harm, not good.

Preventive Treatment.—There is no doubt that chronic atrophic rhinitis is less common than it used to be. The reason for this appears to be that nasal disease is now treated more effectually and patients apply for treatment for nasal symptoms earlier than they used to. Chronic atrophic rhinitis is apt to follow the exanthemata. Especially is this so where obstruction of the nose existed before the occurrence of the eruptive fever. The nasal passages should be very carefully watched, then, during the course of the exanthemata and prompt relief afforded to any nasal obstruction that may occur. This method limits the development of chronic atrophic rhinitis and may prevent it entirely in cases where it would otherwise occur.

Dr. Charles H. Knight said that chronic atrophic rhinitis is one of the diseases for which a great many remedies have succeeded each other year after year. Its treatment is not hopeless in all cases. The affection does not depend only on local conditions, but is often due to a vicous constitutional state, which can be improved by drugs. Where syphilis, or struma, or frank tuberculosis, or the rheumatic or gouty diathesis, or alcoholic bad habits exist, these must be brought under the influence of treatment as effectively as possible and the result will always be an improvement in the nasal condition at least as far as symptoms are concerned. The most distressing symptom is the ozena. This symptom, it must be remembered, may also be produced by syphilitic processes, or by obstruction from deformity or from a foreign body. All of these are very tractable conditions if treatment be prompt. The diagnosis of chronic atrophic rhinitis should not be made, therefore, from the smell alone. A very careful examination should be made to decide that no other cause is at work. The smell in chronic atrophic rhinitis is not in proportion to the amount of secretion, nor to its character. The tissues in some cases seem to have an inherent odoriferous quality, which it is not easy to explain. In treating the ozena, the remedies employed should be already in solution. The use of dry powder in the nose requires the presence of enough secretion to dissolve it, before it can act effectively. This is putting extra labor on tissues that are already lowered in their physiologic function of producing secretion. Crusts that form should be removed with cotton on a probe after a preliminary softening by means of an alkali wash, or atomized oil.

The most useful drug in chronic atrophic rhinitis is menthol. It improves the quantity of the secretion, lessens the tendency to crusting and decreases the smell. A five-per-cent. solution will usually be borne very well at first and may be increased later on. The best fluid application is albolene. It should be used in the form of a spray. When used this way it is not necessary to warm the fluid beforehand. The process of atomization makes the solution cool, no matter how warm it may be originally. Formaldehyde is theoretically an excellent drug to use in chronic atrophic rhinitis. It should act as an antiseptic and as a deodorant. Employed in solutions of 1-5000 it has given good satisfaction. Even thus diluted, however, it sometimes produces irritation. This should be guarded against. It may be employed twice a day after preliminary cleansing with salt solution. Boroformalin is a very good form of the drug to use. Borolyptol has given very good satisfaction in recent years. The ozena is distinctly modified and in certain cases seems to have been practically completely overcome. Ichthyol has given very good results in chronic atrophic rhinitis. It is used in solutions of two to five per cent., the diluent usually being petrolatum. Its unpleasant odor, however, makes it objectionable. Very recently buminol has been recommended, because of its extraordinary antiseptic powers and its absolutely unirritating properties. It is besides an excellent deodorizer. All in all it is the most promising drug at present being used for this bothersome affection.

No operation should be done for the removal of tissue in chronic atrophic rhinitis unless obstruction exists. Where cirrhosis of the submucous tissue has already set in, the ultimate prognosis of the case is not good. At times, however, the development of this sclerotic condition may be prevented.

Some Bacteriology of Atrophic Rhinitis.—In the discussion Dr. Van Sant of Philadelphia said that he had examined 100 cases of chronic atrophic rhinitis in order to decide what bacteria were present. In all of them bacteria were found very plentiful. In 25 of them the pseudodiphtheria bacillus was present. In the first case examined bacteriologically the Philadelphia Board of Health reported that the patient had diphtheria and must be isolated, although he was an ordinary business man going about his avocation every day. There are signs in the general condition of patients suffering from chronic atrophic rhinitis which point to the fact that they are suffering from autointoxication. These toxins are absorbed from septic foci in the nose. Their presence in the circulation causes the sense of lassitude and neurasthenic unrest of which

patients suffering from atrophic rhinitis so often complain. Improvement comes with the use of iron, fresh air, and general hygienic conditions.

Dr. Coyle said that the most useful drug in his practice is hydrozone. After that borolyptol. The best method of treatment seemed to be the insertion of plugs of gauze which are put in with a plug-placer and allowed to remain for twenty-four to thirty-six hours. The tampons themselves do more than any of the remedies that may be employed with them.

Dr. Freudenthal said that the main feature of chronic atrophic rhinitis is the dryness. The main reason for the development of chronic atrophic rhinitis so commonly in this country is the intensely dry air of our houses. In order that the nasal mucous membrane may be comfortable the relative humidity should be at least 60 per cent. As a matter of fact the relative humidity in the living-rooms of our modern houses is never more than 40 per cent., is often less than 30 per cent., and may in steam-heated houses be as low as 15 per cent. When dry air is breathed the mucous membrane keeps giving off moisture constantly. This increase of function finally leads to atrophy, although in the middle turbinate body which does most of the work hypertrophy is usually noticed. Vibratory massage has given the best results in Dr. Freudenthal's hands.

Dr. Douglas said that there are cycles of improvement in chronic atrophic rhinitis almost as in phthisis. It is very hard to decide, then, with assurance what drugs locally or internally used give good results. Two drugs are certainly always of benefit. Ichthyol which may be used in a fifty per-cent. solution, or rubbed in pure, after the employment of a cleansing douche. Ichthyol applications produce a serous exudate and they lead to the absorption of the leucocytic infiltrate. Very recently Dr. Douglas has seen carbon dioxide used under Dr. Achilles Rose's direction with extremely satisfactory results. For atrophic cases with extremely bad odor nothing is more effective. In dry cases with marked atrophy, it seems to do great good in making the erectile tissue more succulent.

Dr. Miles thinks that the etiology of atrophic rhinitis is due to two factors. First, there is imperfect development of the nasal mucous membrane as the result of congenital defect. This mucous membrane becomes a locos minoris resistentiæ. Bacilli attack this mucous membrane in youth and so bring on the atrophic condition. The treatment of the future will undoubtedly be instituted during the preliminary stage, that is some time from two to eight years of age. Ichthyol is the best remedy. It may be used in a twenty-five-per-cent. solution with vaseline or pure on a probe. Iodine internally often does distinct good in these cases, and its use should not be neglected.

Dr. Quinlan thinks that chronic atrophic rhinitis is becoming rarer because more care is taken of the nasal tissues in early life than used to be the custom. Children are brought for treatment as soon as the first symptoms of nasal trouble manifest themselves and so are saved the development of the incurable chronic condition. City children have not enough air and sunshine and are asked to apply themselves too much to their books. The constitutional conditions are certainly important in the development of most nasal conditions and especially of atrophic rhinitis.

Dr. Meyer thinks that after the exanthematic diseases atrophic rhinitis is especially liable to develop. It has been noted that adenoids disappear during an attack of one of the exanthemata. The atrophied condition of the glands of the nasal mucous membrane may be brought about in the same way. The most careful precautions should then be taken to prevent the development of chronic nasal conditions after these fevers.

WESTERN OPHTHALMOLOGIC AND OTO-LARYNGOLOGIC ASSOCIATION.

Held at St. Louis, April 5, 6, and 7, 1900.

The President, W. Scheppergrell, M.D., in the Chair.

The President opened the meeting with a paper on "The Rise of Specialism," in which he disproved the oft-repeated charge that specialisms in medicine are modern innovations. He cited historical data dating several centuries before Christ in which distinct references were made to specialists of the eye, stomach and the head. The essayist commended specialists in medicine, as they promote more detailed study and thereby lead to higher medical attainments.

J. W. Bullard, M.D., of Pawnee City, Neb., read a paper on "Two Classes of Eye Cases That Give a Great Deal of Trouble." Chief among them were those in which irritation and dryness of the conjunctiva persisted in spite of every attempt at refraction which had been made.

Edwin Pynchon, M.D., of Chicago, read a paper, entitled "Slight Irregularities of the Nasal Septum." The author advocated the removal or correction of slight irregularities of the septum when there were disturbances of the nasal functions on account of their presence. If later and larger developments justified their removal, the author thought their early removal was justified on the grounds of "A stitch in time saves nine."

C. R. Holmes, M.D., of Cincinnati, read a paper on "Foreign Bodies of the Orbit, with Report of Cases." About seventy cases were compiled from the literature by the author and three additional ones were reported by him. The most interesting and unique case was one reported by the author. It consisted of a knife-blade about 1-1½ inches long which had been in the orbit thirty-two years without causing much inconvenience. It was imbedded in a fibrous capsule and was but slightly rusted.

M. A. Goldstein, of St. Louis, reported two

cases, *viz.:* (a) Primary Tuberculosis of the Ear; (*b*) Primary Tuberculosis of the Larynx. (*a*) The case had been operated on some years previously and had a recurrence some months ago, at which time Dr. Goldstein did the Schwartz operation. Bad symptoms developed a few weeks ago and he did the radical operation, since which time the patient has been doing well. (*b*) The second case was one of probably primary tuberculosis of the larynx, which came under the observation of the author about one year ago. At that time he was in a very serious condition; death seemed but a matter of a few weeks or months. The patient was growing greatly emaciated, and in response to the treatment administered had gained a fair degree of health, being able to attend to business. The diagnosis in the case is somewhat doubtful, but the author, having excluded lues and malignant growth, has made the diagnosis of primary laryngeal tuberculosis. Tubercle bacilli are absent and the tissue has not been examined microscopically.

Dr. Wm. L. Ballenger, of Chicago, read a paper on "The Physiologic Tests of the Organ of Hearing as Aids in the Differential Diagnosis of Lesions of the Ear." The author advocated the physiologic tests of the ear, including the range of hearing, as tested with the tuning-fork, Galton whistle, the Webber experiment, the Rinne experiment, the Schwaback and Bing tests, as important aids in the differential diagnosis of the lesions of the ear. They are of special importance in determining the location of the lesion. He suggested that in a general way the deeper the structure involved, the more pronounced the disturbance of hearing and the less probability of a cure. The tests were therefore recommended more for the purpose of aiding the surgeon in giving a correct diagnosis than for the purpose of aiding him in the treatment, which is often unsuccessful. Six cases were cited illustrating lesions of different kinds in the middle ear and labyrinth, in which the tests were used for the purpose of differentiating them. He recommended that the tests be made in all cases of ear disease in which there was marked deafness and tinnitus, both before and after the inflation of the tympanum. If this point is neglected the diagnosis may not be properly made. While the physiologic tests are not absolute guides to a correct diagnosis, they are, together with all other means of diagnosis, the most correct at the command of the aural surgeon and therefore should be invariably used.

O. J. Stein, M.D., of Chicago, read a paper entitled, "Symmetrical Osteoma of the Nose: Report of a Case." The author reported a very rare case of symmetrical or double osteoma of the nose, occluding the nasal chambers and extending to either side for a considerable distance, whereby the patient was given the typical frog-face appearance. Osteoma upon one side is rather common. This case was presented on account of its unique type and was reported with a number of other cases collected from the literature. No attempt was made to correct the deformity, as the patient is well advanced with tuberculosis, several other members of the family having died with the same disease.

J. O. Stillson, M.D., of Indianapolis, read a paper on "Removal of the Middle Turbinate for the Cure of Some Forms of Inveterate Eye Disease." The author read a very interesting paper upon this subject in which he reported his observations as to the relationship of nasal and eye diseases and the results he had obtained in allaying eye symptoms by the treatment of nasal conditions, more especially the removal of the turbinate.

Dr. Goldstein, as Chairman of the Local Committee of Arrangements, arranged for a museum of pathologic and anatomic specimens which, while not large, was extremely interesting and marks a new departure in this society.

Dr. M. A. Goldstein of St. Louis was elected president for the ensuing year.

REVIEWS.

The Treatment of Diseases of the Nervous System. A Manual for Practitioners. By Joseph Collins, M.D., Professor of Nervous and Mental Diseases in the New York Post-Graduate Medical School; Visiting Physician to the New York City Hospital. Illustrated by Twenty-three Engravings. Cloth. Pp. 602. New York: William Wood and Company, 1900.

Among the various books on nervous diseases this work stands out as promising to be one of the most useful to the general profession. The aim of the author is to present in detail to the general practitioner the best and latest treatment of diseases of the nervous system. This he has succeeded in doing, symptoms and etiology being secondary considerations, although etiology is presented fully but concisely, because of its relation to the conscientious treatment of the diseases.

The book is divided into three parts. Part I. treats of the causes and origination of diseases of the nervous system in general and of the prevention of these diseases. The chapter on general etiology is well worth reading and should be read by every general practitioner. It presents the subject in a comprehensive form, each factor being considered in detail. As to the rôle of infection, the author thinks that such diseases as beriberi, Landry's paralysis, and anterior paliomyelitis, which are thought to be due to some specific organisms, will be found, when these organisms are isolated, to be due in reality to bacteria which cause more common diseases in other parts of the body. In other words, he does not think that any disease of the nervous system is dependent on an

organism that causes a specifically nervous disease.

Diseases of the nervous system due to syphilis are divided into syphilitic and parasyphilitic. The genuine syphilitic diseases are subdivided into: (1) Syphilitic disease of the blood-vessels; (2) syphilitic disease of the parenchyma of the central nervous system; (3) syphylitic disease of the coverings of the central nervous system, particularly the meninges; (4) syphilitic new formations of sufficient size to deserve the name of tumor; and (5) syphilitic neuritis, a condition that is rare, but whose actual occurrence would seem to be fairly well substantiated.

The parasyphilitic diseases, which are always degenerative *ab initio*, are: (1) Tabes dorsalis; (2) general paresis; and (3) some neuroses, including syphilitic neurasthenia, epilepsy, neuralgia, and possibly hysteria. The author believes that antisyphilitic treatment has little if any influence to prevent the occurrence of parasyphilitic diseases of the nervous system. In the chapter on prevention, a number of pages are devoted with advantage to the education and bringing up of the neuropathic child.

Part II. treats of the general application of remedial measures in the treatment of nervous disease. There are seven chapters, one each on drugs, hydrotherapy, electrotherapy, massage, exercise, rest and occupation, diet, and psychotherapy. In the chapter on drugs, the use of tetanus antitoxin and the thyroid gland, with the methods of their administration, is considered. The abuse of opium and the bromides is discussed, and a number of drugs useful in diseases of the nervous system are considered in detail, with points as to the best preparation, dosage, and manner of administration of each. The value of hydrotherapy, electrotherapy, and massage is discussed in the following three chapters, and the various forms, manner of application, length of each treatment, the diseases benefited, and the results to be expected from each form of therapy are considered. The chapters on diet and psychotherapy contain many useful suggestions.

In Part III., which considers the treatment of individual diseases, the author has made no attempt at classification, but has taken the subjects up in the following order: Diseases of the brain, of the spinal cord, of the peripheral nerves, of the sympathetic nervous system, the functional nervous diseases, and, finally, the most common symptomatic manifestations, such as headache, delirium, convulsions, hemiplegia, and insomnia.

The etiology of the various diseases is given rather fully, the symptoms are portrayed in as few lines as possible, while the treatment, in accordance with the purport of the book, is considered fully and in detail. The author has given proportionately much more space to the discussion of headache, neurasthenia, vertigo, and other functional and symptomatic states than to most of the organic diseases, for the reason that the former occur more frequently and cause more suffering. In considering the treatment of tabes, Fraenkel's method of re-education of the ataxic extremities is described and illustrated by a few engravings.

On the whole, this work of Collins is exceedingly good and will prove of interest and value to every general practitioner as well as to specialists in this branch of medicine.

The volume is illustrated by twenty-three engravings. It is disappointing that an otherwise admirable book should be printed on such a poor quality of paper as is used in this.

A System of Medicine by Many Writers. Edited by THOMAS CLIFFORD ALBUTT, M.D., M.A., etc., Regius Professor in the University of Cambridge; Fellow of Gonville and Caius College; Hon. Fellow Royal College of Physicians of Ireland. Volume IX. New York: The Macmillan Company.

THE present volume contains quite an assortment of topics. About 170 pages are devoted to a number of the neuroses. Craft Palsies, Torticollis, Tics, Paralysis Agitans, Migraine, Hysteria, Latah, Catalepsy and Neurasthenia are included here under this title. These are all excellent treatises, that on Neurasthenia, by the editor, being especially noteworthy. It is also worthy of note that migraine is considered as a toxic disease affecting the sympathetic nervous system. The section on Mental Diseases occupies over 250 pages, and, while not a complete treatise on insanity, it contains a number of suggestive articles by well-known writers. Dull, Delicate and Nervous Children by Frances Warner, and Vice, Crime and Insanity, by Dr. Mercier are valuable and forceful presentations of subjects now prominent in discussion. The chapter on Epilepsy and Insanity is also to be commended. The treatment of the main types of insanity, to which a special chapter is devoted, offers much that is new and suggestive.

The remainder of the book is concerned with Diseases of the Skin, these occupying 500 pages. The discussion of the various skin lesions is excellent, but the restrictions in the matter of illustrations render this portion of less value to the practitioner than many modern works on dermatology. The present volume is well up to the excellent standard of the others.

Twentieth Century Practice. An International Encyclopedia of Modern Medical Practice. By Leading Authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City. Volume XVIII. "Syphilis and Leprosy." New York: William Wood and Company., 1899.

THE eighteenth volume of this well-known system of medicine opens with a comprehensive description of acquired syphilis by Professor Lang of Vienna. "We have every reason to look for a living organism in the syphilitic contagium;

but as we have not yet found it, we are unable to give a precise definition of syphilis. We must at present be satisfied to characterize the disease by enumerating the effects produced by the contagium." The author gives a good account of the variety in clinical appearance and distribution of the initial lesion. The account of syphilis of the nervous system is thorough, as is that of the osseous system. The description of joint syphilis is very meager. In the account of the blood changes in syphilis we are surprised to find a statement as manifestly incorrect as this: "Ehrlich discovered that the presence of cells with neutrophile eta-nuclei is characteristic of myelogenous leucemia." The author evidently is not well versed in modern blood pathology. We are glad to observe that due credit is given to the work of American syphilologists. The author is a firm believer in electric cataphoresis and extols the value of the electric sublimate baths.

Only twenty-eight pages are devoted to the subject of inherited syphilis, by Jonathan Hutchinson of London. More space should have been given to this important subject. From a recognized authority, as is Dr. Hutchinson, we expected much more than the meager account he has written.

Dr. Prince A. Morrow of New York contributes a long paper on "Leprosy" and gives a good description of the various stages and manifestations of the disease. The illustrations are excellent. The account of the geographical distribution of the disease and the methods of dealing with it in ancient and modern times is admirable and shows that the writer has a thorough knowledge of the literature of the subject.

Diseases of Women. A Treatise on Principles and Practice of Gynecology for Students and Practitioners. By E. C. Dudley, A.M., M.D., Professor of Gynecology in the Northwestern University Medical School, Chicago. Second Edition, Revised and Enlarged. 8vo., 717 pages. Illustrated. Philadelphia and New York: Lea Brothers & Co.

This second edition is even more attractive than the first and has some additional chapters, although the volume is preserved in its original convenient form. The plan of dividing the subject on the basis of pathology, which is a characteristic feature of the book, has been retained. The functional disorders of menstruation and sterility, although still recognized as symptoms only, have been skeletonized and presented in four new chapters. This addition introduces also thirty-one new engravings and six new full-page plates. The abundance of colored plates and pictures form an especially attractive and desirable feature.

There are one or two points in which we had looked for improvement. One was in reference to the teachings regarding the function of the perineum. We are surprised to find the author still declaring that the perineum is a support to the uterus. The abdominal muscles support the head, but we do not often speak of them in that connection.

In the chapter on perineorrhaphy the author has confined himself to one procedure, namely, the Emmet operation, and, although he has made this comparatively plain, it still remains a complicated procedure and difficult for the majority of the profession to undestand. There are other and simpler operations that give quite as good, if not better, results. In a work for students it would seem desirable that they should at least have the opportunity of understanding and adopting them. Each subject is concisely and definitely treated, and it is evident that the author relies upon his personal experience to justify his teaching. No recent book presents the practical side of gynecology in so complete, attractive and available a form.

A Pocket Text-Book of Diseases of Women, by Montgomery A. Crockett, A.B., M.D., Adjunct Professor of Obstetrics and Clinical Gynecology, Medical Department of the University of Buffalo, N. Y. Lea Brothers & Co., Philadelphia and New York. Price, $1.50.

This new volume of the series is in no way inferior to the volumes which have preceded it. The author has not forgotten that clearness and conciseness are, for the student, of the foremost importance; yet the completeness of the text will make it no less welcome to the practitioner. The first three chapters are devoted to a general discourse on diagnosis, local treatment and gynecological operations, which in every way conform to the latest concepts of the science. In the discussion of the separate diseases, the important subject of genital tuberculosis receives a separate chapter. A great deal of care has been bestown on the explanation of the mechanism in versions and flexions. The author is especially to be congratulated upon the successful way in which he has presented the difficult subject of ectopic gestation. Several minor subjects, such as kraurosis vulvæ have, on the other hand, received no mention whatsoever. The most important operations are mentioned in detail and the clearness of the text is still further enhanced by a number of excellent illustrations. The book is to be recommended as one of the best of the shorter treatises on gynecology.

Die Technik der speciellen Therapie. Ein Handbuch für die Praxis von Dr. F. Gumprecht, Professor in Jena. Zweite Auflage. 8vo., 354 pages. Illustrated. Gustav Fischer. Jena. Seven marks.

For the general practitioner certain routine examinations in the realm of the specialist are indispensable. To gain command of the methods of examination of special regions and to be able to treat the common ailments to which such regions are subject, the greater number of practitioners must attend post-graduate courses. In such courses treatment of the affections of the nose and throat, the stomach and intestines, the

bladder, etc., is learned by actual work with the patient. The present volume serves the purposes, in large measure, of just this type of post-graduate instruction. It contains discussions, in brief, of the anatomy and physiology of a given region, and then describes the instruments used in the treatment of the more common diseases of the regions, with full detail as to the correct procedures. In addition it gives reasons why certain methods of treatment are advisable and discusses quite fully the *rationale* of a large number of technical applications.

An abbreviated list of the subjects treated is here given: Puncture and incision of the skin, blood-letting, transfusion, and vaccination; esophageal sounds and their uses, washing of stomach, feeding by esophageal tubes, electrical treatment of the stomach and intestines, massage of the intestines; treatment of the upper air passages, mouth, nose, pharynx and larynx; thoracentesis, drainage of chest and pericardium; abdominal puncture; lumbar puncture, and technical procedures for the genito-urinary tract.

The work is a valuable one for the student and the practitioners removed from the facilities of clinics and clinical instruction.

Sixth Annual Report of the Board of Managers of Craig Colony at Sonyea, N. Y. To the State Board of Charities. 1899.

The report of this Board, of which Dr. Frederick Peterson is president, is of interest as it shows the development of one of the newest and most important branches of State charity. Since the opening of the Colony, February 1st, 1896, there have been received 504 epileptics, of whom 378 remain. During the past year 95 cases were admitted and 39 discharged. When the buildings now being erected are finished, the Colony will be able to care for 720 cases. There are already more than enough applicants to fill the additional beds.

All improvements during the last year have been made within the limits of the appropriations. Among the needs of the Colony for the coming year are dormitories and infirmaries, and for this purpose an appropriation of $100,000 is asked. Among other appropriations asked for is $4000 for scientific research. The death-rate for the past year was less than two per cent. The good results of treatment and life at the Colony have been more marked the past year than in previous years.

The Nervous System of the Child. Its Growth and Health in Education. By Francis Warner, M.D., Physician and Lecturer at the London Hospital. New York: The Macmillan Company.

The impulse which was given by Preyer to the study of child-life has produced within the past five years a veritable avalanche of treatises on the various attributes of child-life. None has been more interesting than those devoted to child-psychology. While we have yet to see a presentation of the child's development as comprehensive and as suggestive as that of Preyer, this volume presents a number of features that are specially commendable.

The author's standpoint, the child's relation to education and the school, is especially engaging, since so much is hoped for in education and often so little is realized. As a guide for teachers and parents who desire to observe their children closely and wish to correct faulty habits of work and encourage fruitful lines of activity, the present volume is to be warmly commended.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

The Soul of Man. By Dr. Paul Carus. Second edition. 12mo., 482 pages. Illustrated. Chicago. The Open Court Publishing Company.

The Irrigation Treatment of Gonorrhea. Its Local Complications and Sequelæ. By Dr. Ferd. C. Valentine. 8vo., 221 pages. Illustrated. New York. William Wood and Company. $2.00.

Venereal Diseases, their Complications and Sequelæ. By Dr. E. L. Keyes and Dr. C. H. Chetwood. 8vo., 356 pages. Illustrated. New York. William Wood and Company. $2.75.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Dr. Hobart Amory Hare. Vol. I. March, 1900. 8vo., 428 pages. Illustrated. Lea Brothers and Co., Philadelphia and New York.

The Anatomy of the Brain. A Text-Book for Medical Students. By Dr. Richard H. Whitehead. 8vo., 96 pages. Illustrated. F. A. Davis Co., Philadelphia. $1.00.

Injuries to the Eye in their Medico-Legal Aspect. By Dr. S. Baudry. Demi 8vo. 161 pages. Illustrated. F. A. Davis Co., Philadelphia. $1.00.

The International Medical Annual and Practitioners' Index. A Work of Reference for Medical Practitioners. 8vo., 747 pages. 1900. E. B. Treat & Co.

FIFTH TRIENNIAL CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS, WASHINGTON, D. C., 1900.

*THE MEDICAL SCHOOL OF THE FUTURE.**

BY H. P. BOWDITCH, M.D., LL.D.,
OF BOSTON;
PRESIDENT OF THE CONGRESS.

AMONG the intellectual movements that have characterized the century now drawing to a close there is perhaps no one more deserving of careful study than that which is concerned with providing education for the people in the school, the academy and the university. The importance of popular education became apparent in proportion as political freedom was secured for the people. Thus Viscount Sherbrooke, better known as the Hon. Robert Lowe, in the reform debates of 1866 and 1867, after the passage of a bill for the extension of the suffrage, uttered the well-known words: "We must now at least educate our masters." The same sentiment has also more recently been embodied in the inscription on the Boston Public Library. "The Commonwealth requires the education of the people as the safeguard of order and liberty," and in the presidential address of Dr. J. M. Bodine[1] at the meeting of the Association of American Colleges in 1897 we find the same idea thus expressed. "In America the citizen is king. The king must be educated to wield aright his hallot-sceptre."

For many years educators looked upon their work with no little complacency. The educational systems of the various civilized countries were supposed to be well adapted to the ends in view, and educational exhibits have generally been regarded as important features of international expositions. But within the memory of most of those now before me signs of serious discontent have not been wanting. Education has not always been found to furnish the required safeguards for order and liberty. Highly educated men have often been found singularly lacking in mental balance. Schools for the inculcation of "common sense" have never yet been established. Even the great development of psychology as an experimental science, which has occurred chiefly within the last twenty-five years, although it has served to establish many laws of mental action, has thus far failed to justify the hope that pedagogy may find in psychology a foundation for the erection of rational systems of education. Indeed we have recently been told by one of the ablest expounders of this science that it is a great mistake for teachers to "think that psychology, being the science of the mind's laws, is something from which they can deduce definite programs and schemes and methods for immediate school-room use. Psychology is a science and teaching is an art. A science only lays down lines within which the rules of the art must fall, laws which the follower of the art must not transgress; but what particular thing he shall positively do within those lines is left exclusively to his own genius."[2]

Even this general guidance has been very imperfectly afforded, for the limits set by the science of psychology to the art of teaching have never been precisely defined. In fact the most fundamental question of all, *viz.*, the relation of mental to physical development has not yet been settled, although much material for its study has been collected. It is not, therefore, surprising that in many countries teachers have made too great demands upon the time and strength of growing children.

This has been clearly the case in Germany, where schoolboys from eight to fifteen years of age have found their vital energy so far exhausted by the school-work required of them that they have lost all inclination for vigorous athletic amusements so naturally indulged in by Anglo-Saxon boys. The deterioration of the race as a result of too close application to intellectual pursuits, to the neglect of the physique, has been fortunately obviated, in the case of Germany, by the army system which takes entire possession of the youth before it is too late and, by requiring him to devote three years to the education of his body, turns him out, at the end of that period, a young man with mind and body trained to a high degree of efficiency, well fitted for civil as well as military pursuits and comparing favorably in all respects with men of his age in other nations. Looked at from this point of view the German army must be regarded as an important part of the educational system of the country, although as a piece of educational machinery its workings cannot be considered economical. In fact, the absurdity of depending on the army to remedy the defects of the school system has long since been forced upon the attention of German educators and the difficulties above alluded to are now in a fair way to be removed.

In our own country difficulties of quite a different kind have been met with. Here the great danger which threatens our system of popular education arises from its close association with party politics. The office of a school committeeman in one of our large cities has been well de-

* President's Address.

scribed as "the smallest coin in which politicians pay their debts" and as long as the education of our children continues to be entrusted largely to men who consider their position on a school board as the lowest step of the political ladder, there is small hope of the adoption of rational methods of education. Moreover, this intimate alliance between education and politics greatly aids the efforts of persons more zealous than discreet to direct the instruction of children in accordance with their own special views. Thus, nearly all the States of the Union have upon their statute books laws requiring the physiological action of alcohol to be taught to children in all grades of the public schools. These laws violate the first principles of pedagogy inasmuch as the physiological action of a drug cannot possibly be understood without a familiarity with anatomy, physiology and chemistry which school children cannot be supposed to possess. They have been passed at the bidding of total abstinence associations, sometimes in opposition to the earnest protests of the teachers entrusted with their execution. How these excrescences upon our educational system may be best removed and the work of instruction placed under the control of those best qualified to direct it are questions demanding serious consideration.

I have mentioned these instances in which great educational systems have been found wanting merely for the sake of pointing out that the critics of our methods of medical education, who, as Professor Exner[3] has shown, are now raising their voices in every land, do but give a special expression to a wide-spread feeling that our educational systems are not accomplishing all the objects for which they have been devised, and that the discontent which they imply is but a healthy dissatisfaction with the results thus far accomplished. May the time be far distant when those in charge of our educational interests shall rest content with what they have achieved, for this will indicate that a state of stagnation has been reached similar to that which characterizes the institutions of the Celestial Empire and that no further attempt is to be made to adapt our methods of instruction to the constantly widening domain of human knowledge and experience.

It may, perhaps, be well for me at this point to offer a few words in explanation of the selection of such a well-worn theme as medical education as the subject of my remarks this evening. It is true that in recent years the subject has been a favorite one with those who have been called upon to address medical associations or classes of graduating students and if, in spite of this fact, I venture to add another address to the fast growing literature of the subject, my justification may be found in the following reasons. In the first place, it must be borne in mind that such addresses are very quickly forgotten. "Were it not so," as Dr. Billings has remarked, "it would be a hard world for address-givers." In the second place, the progress of medicine at the present time is so rapid that new points of view are constantly being secured and it is, therefore, not at all impossible that, even at comparatively short intervals, new and valuable suggestions may be made both with regard to subjects to be taught and to methods to be employed in giving the instruction.

Lastly, it so happens that during the academic year now nearly completed, the faculty of the Harvard Medical School has inaugurated an entirely new plan of instruction in the sciences of Anatomy, Physiology and Pathology. This scheme, although still in the experimental stage, embodies ideas of such fundamental importance in medical education that its presentation to a representative body of the medical profession seems to me to be peculiarly appropriate.

I shall therefore ask you to consider with me this evening what lessons the faculty of a modern medical school may draw from recent advances in medical science and recent experience in medical education or, in other words, on what lines the instruction of a medical school of the first rank is likely, in the immediate future, to be organized. I say in the *immediate* future, for what changes are in store for us in the course of the next few decades it is equally impossible to foresee and useless to speculate.

Relation of Medical Schools to Universities.—One of the most hopeful signs of the times in the field of medical education is the growing tendency of the better schools to ally themselves to Universities and of Universities to establish Medical Departments. Of the great advantages to medical education which may be expected from this union it is unnecessary for me to speak, for they formed the subject of a thoughtful discourse delivered by the last president of this Congress at Yale University in 1888.[4] The twelve years that have elapsed since he spoke have brought accumulating evidence of the soundness of his views. In fact, it is difficult to see how a private medical school of the joint stock company type can ever, in the future, rise to the first rank, for such a school is not much more likely to attract endowments than a cotton mill, and without endowments the enormous expenses of a modern first-class medical school cannot possibly be met.

Great as are the benefits to a medical school of thus forming a department of a great university, the advantages of the union are not wholly on one side. Beside the increase of prestige secured to the University by the broadening of its functions, the establishment of a medical school as part of the university organization greatly facilitates the instruction of those students who, without any intention of becoming physicians, seek in the study of the medical sciences a means of general culture and mental discipline.

The relations between the governing body of a University and its medical faculty in matters of administration are often defined by custom and tradition rather than by statutory provisions and vary considerably in different institutions. In general two methods of government may be distinguished. Either the initiative is left with the

teaching faculty, the governing body exercising simply a veto power, or the governing body acts directly without necessarily asking advice from the faculty or its members. The former method of government is most likely to be found in those cases in which a well-established medical school has allied itself to a University for the sake of the mutual benefits that may ensue from the union, and the latter method in those cases in which a University has completed its organization by the creation of a medical department. Both methods have certain advantages and neither is without its drawbacks. In all cases men are more important than methods. On the one hand, the collective judgment of a teaching faculty on matters relating to medical education is likely to be of more value than that of a governing body which may not, and generally does not, include physicians among its members. On the other hand, personal and selfish considerations are perhaps more apt to sway the judgment of a faculty than that of a body of trustees, especially when the question is that of the appointment of teachers. That this is not a serious danger, however, the experience of Germany seems clearly to show, for in that country, as Dr. Farlow has recently pointed out, the faculty "has more power in regard to appointments and the general policy of the university"[5] than with us, and yet we find there the custom of calling professors from one university to another fully established, a custom which must be regarded as one of the strongest influences in maintaining a high standard of educational efficiency. On the whole, therefore, even with this possibility of error, the judgment of a faculty would seem to be the safer guide and there are probably few boards of trustees who would feel themselves justified in disregarding it altogether.

The above-mentioned advantages of a union between a medical school and a university will naturally become more obvious as the problems of medical education become more complex and the methods of instruction more costly. Hence we may expect in the near future to find all of the better class of medical schools under the ægis of a University and we may reasonably hope that this change will be associated with a diminution of the total number of medical schools now so greatly in excess of the needs of the country.

The union of a medical school with a university at once compels the consideration of the proper relation between the academic department and the professional school. To say that the former should be the feeder of the latter and that the holding of an A.B. degree should be the condition of admission to professional studies, is to adopt the position taken by two of our leading medical schools. The A.B. degree, however, since the introduction of the elective system, no longer stands for a definite amount and kind of training. Hence, the Johns Hopkins Medical School demands not only the diploma but also evidence of ability to read French and German and of laboratory training in physics, chemistry and biology. The Harvard Medical School is content to accept the A.B. diploma as evidence of fitness to pursue professional studies, stipulating only that the holder shall possess an adequate knowledge of inorganic chemistry. Whether the example set by these schools will be generally followed is quite doubtful. Without undervaluing the importance of collegiate training as a preparation for a professional career it may perhaps be contended that a properly conducted admission examination is a better test of fitness to pursue the study of medicine than the possession of a diploma, the value of which varies so much with the character of the college bestowing it. Moreover, the possibility that a young man, unable to afford the expense of a college course, may yet by private study prepare himself for a professional career is not to be lost sight of. Hence, the Harvard school provides for the admission by special vote of the faculty of young men not holders of an A.B. degree, who may furnish satisfactory evidence that they have obtained an equivalent education and that they are consequently able to profit by the instruction which the school has to offer.

The recent lengthening of the course of study from three years to four, in all the best medical schools of the country, has drawn renewed attention to the importance of enabling the student who takes the A. B. degree as a preparation for medicine to so far shorten the sum total of the time devoted to his education that he may be able to enter upon the work of his profession at an age not in excess of that at which his European confrères begin their career as practitioners. A few years ago an examination of the best accessible evidence on the subject led to the conclusion that foreign systems of university education enabled students of medicine to enter upon their life-work at least two years earlier than was possible for the alumni of Harvard College, a condition dependent upon the fact that the changes in the academic department which had raised the age of graduation had been made with little regard to the interests of the professional schools and chiefly for the purpose of making the undergraduate department as complete as possible in itself. In other universities a similar condition existed, although probably not in the same degree, as in Harvard.

That the American medical student, seeking the best possible preparation for his profession, is seriously handicapped by these conditions has been generally recognized and the question of the best method of meeting the difficulty has been widely discussed. The most thorough treatment of the case consists in reducing the academic course to three years. Less radical methods are the provision in the academic department of courses of instruction by which students may anticipate a part of their professional work and the permission to count the first year of a professional course as the fourth year for the bachelor's degree. The first and most radical method meets with strenuous opposition owing to the deeply

rooted traditions which surround the four years' academic course in this country, while the other plans violate what in some colleges seem to be regarded as an educational axiom, that one course of study should not count toward two degrees. It is interesting to notice that, without any specific legislation to this end, the quiet working of the elective system has in Harvard College practically solved the problem by bringing about a condition in which, as President Eliot says,[6] "Any young man of fair abilities can now procure the degree in three years without hurry or overwork, if he wishes to do so or his parents wish to have him." The President further ventures to predict that "within a time comparatively short the majority of those who enter the freshman class will come to college with the purpose of completing the requirement for the degree in three years." As soon as a three years' residence becomes the rule rather than the exception, a young man spending four years in college will, of course, be regarded either as deficient in mental capacity or as having wasted his time.

That a reduction of the academic course to three years is an advantage to students looking forward to a professional career or to further study in a graduate school is too obvious to need discussion, but it is interesting to find the change advocated in the interest of the undergraduates themselves. Professor Clement L. Smith, for nine years Dean of Harvard College, points out[7] that there is a large and influential class of college men who get into the habit of frittering away their time simply because they have so much of it and that "for them and for those whom they influence—and these make up the largest part of the class we are now considering, the men who go from college into active life—the reduction of the course would be a distinct gain." Nor need we fear (as has sometimes been urged) that, in thus reducing the length of the college course, we shall lose the fourth and most valuable year, for, as Professor Smith says, "The senior year is the best year, not because it is the fourth, but because it is the last year. The causes which make it what it is come from before, not from behind; from the consciousness of opportunity passing away and of the serious problems of life close at hand. The period of waste lies between the fresh zeal and good resolutions with which the youth begins his course, and the growing sense of responsibility with which he draws near its close. It is this intermediate period that would be shortened in the briefer course. It is not the senior year that would be cut off; it is rather, let us say, the sophomore year, and with it might well go its absurd name."

It thus appears that the claims of the college and of the professional school upon the time of the students are in a fair way to be harmoniously adjusted .

Elective System.—Let us now consider in what way the medical school of the immediate future is likely to differ from that of the present time with regard to the subject matter of instruction. The most striking phenomenon presenting itself to the educator of to-day is the recent enormous widening of the educational horizon. "The immense deepening and widening of human knowledge in the nineteenth century and the increasing sense of the sanctity of the individual's gifts and will power"[8] are the fundamental facts which underlie the development of the elective system, but it is important to bear in mind that, as Professor Smith observes,[9] this development has been "due not so much to increase of knowledge—for not all new knowledge is straightway fit for educational purposes—but rather to the conversion of new fields of knowledge to the uses of education."

A discussion of the elective system of education with its attendant advantages and dangers would require far more time than I have at my disposal and I must content myself with pointing out the possibility that, in this period of transition, the educational pendulum may have swung to an extreme position and that too much attention has been given to the accidental differences of pupils while the essential similarity of their natures has been lost sight of. In discussions on individuality as a basis for the elective system one sometimes hears the statement (attributed to Leibnitz) that no two leaves of the same tree are alike. This dissimilarity, however, does not prevent them from all elaborating the same sap, and it is, moreover, always associated with sufficient essential similarity to enable any one, with even the most elementary knowledge of trees, to distinguish the leaves of an oak from those of a maple.

While admitting that some of the extreme positions now maintained by the advocates of the elective system may in the future have to be abandoned, no one can doubt the wisdom of adapting the education to the powers of the mind to be educated and of allowing, in the case of advanced students, the choice of the individual to be a determining factor in the selection of studies. Let us, therefore, enquire to what extent the elective system may properly find a place in the curriculum of our medical schools. That it forms an essential feature of our post-graduate schools of medicine scarcely needs to be mentioned, for these schools have been organized for the express purpose of enabling graduates in medicine to select such subjects for study as may seem to them desirable and to acquire more advanced knowledge than was possible in the undergraduate course. Moreover, in some of our larger schools, since the establishment of the compulsory four years' course, a portion of the instruction of the fourth year has been given in elective courses in various specialties. The elective system in medicine is, therefore, not altogether a novelty and the question now before us is whether it may be profitably extended to the earlier years of the course.

In his remarks at the dinner of the Harvard Medical Alumni Association in 1895, President Eliot used the following language: "There ought

to be in the Harvard Medical School an extended instruction far beyond the limits of any one student's capacity. This involves, of course, some optional or elective system within the school itself, whereby the individual student should take what is, for him, the best four years' worth, the faculty supplying teaching which it might take a single student eight, twelve or twenty years to pursue."[10]

One year ago last December, in an address which I had the honor to deliver in New York before the American Society of Naturalists,[11] I gave the reasons which seemed to me conclusive in favor of this extension of the elective system, and, with your permission, I will take the liberty of presenting as briefly as possible the views there set forth.

In the first place, it may be assumed that a medical school of the first rank should be an institution in which the most advanced instruction in all departments of medicine can be obtained, and on this assumption it is, of course, impossible to arrange a course of study that every student must follow in all its details, for, in the time which may properly be devoted to a course of professional study, it is quite impossible for even the most intelligent students to assimilate all the varied information which such a school may be reasonably expected to impart.

It seems, therefore, to be evident that in arranging a course of medical study a distinction must be made between those subjects which it is *essential* that *every* student should know and those subjects which it is *desirable* that *certain* students should know, that is, between those things of which no man who calls himself a physician can afford to be ignorant and those which are important for certain physicians but not for all; in other words, provision must be made both for required and for elective studies. The task of drawing the line between the essential and the desirable in medical education will require the greatest possible good judgment and readiness for mutual concession on the part of those engaged in the work, but there is no reason to fear that the difficulties will be found insuperable when the importance of the change has once been recognized.

Any one who is familiar with the existing methods of medical instruction is aware that in nearly every department many things are taught which are subsequently found to be of use to only a fraction of those receiving the instruction. Thus, the surgical anatomy of hernia is taught to men who will subsequently devote themselves to dermatology, future obstetricians are required to master the details of physiological optics, and the microscopical anatomy of muscles forms a part of the instruction of men destined to a career as alienists. Now no one can doubt the propriety of including instruction on all these subjects in the curriculum of a medical school, but it may be fairly questioned whether every student should be forced to take instruction in them all.

To better indicate the nature of the reform which I am advocating, allow me to describe a possible arrangement of a course of study in the department of physiology, with which I am, of course, more familiar than with any other. An experienced lecturer will probably find it possible to condense into a course of about forty or fifty lectures all the most important facts of physiology with which every educated physician must necessarily be familiar. Attendance upon these lectures, combined with suitable courses of text-book instruction and laboratory work, would suffice to guard against gross ignorance of physiological principles. In addition to this work, all of which should be required, short courses, of not more than eight or ten lectures each, should be provided, giving advanced instruction in such subjects as the physiology of the special senses, cerebral localization, nerve-muscle physiology, the internal secretion of glands, the physiology of the heart, circulation and respiration, the digestive secretions, the reproductive organs, etc. These courses should be elective in the sense that no student should be required to take them all. Each student might, however, very properly be required to choose a certain number of courses, which, when once chosen, become, for the student choosing them, required courses leading to examinations. There is, in my opinion, no doubt that an arrangement of instruction similar to that here suggested for physiology could be advantageously adopted in the departments of anatomy, histology, bacteriology, medical chemistry, pathology, surgery, and in the courses of instruction in the various special diseases, such as dermatology, ophthalmology, etc.

In the existing state of medical education the introduction of the elective system in some form or other seems to be an essential condition to any further important advance, for the curriculum of most of our schools is already so crowded that no considerable amount of instruction can possibly be added. Various arguments may, of course, be advanced in opposition to the change. It may perhaps be urged that no choice of studies can be made without determining to some extent the direction in which the work of a future practitioner is to be specialized and that such specialization cannot be properly and safely permitted until the student has completed his medical studies. To this it may be answered that, whatever may be the dangers of too early specialization, the dangers of crowding the medical course with instruction of which many students do not feel the need, and of thus encouraging perfunctory and superficial work, are certainly no less serious. It is, moreover, a matter of common observation among teachers in medical schools that a certain number of students very early make up their minds either that they will become surgeons, obstetricians, or specialists of some sort, or, on the other hand, that they have a strong aversion to certain branches of medicine and a determination never to practise them. For such students a prescribed curriculum necessarily involves great loss of time and energy.

If it be said that under this system the medical degree will cease to have the definite meaning now attached to it and that it will be impossible to tell from his diploma in what way a physician has been educated, it may be replied that, although the degrees of A.B., A.M., Ph.D. and S.D. are affected with exactly this same uncertainty of signification, their value seems in no way diminished thereby. As long as the M.D. degree stands for a definite amount of serious work on medical subjects, we may be reasonably sure that those who hold it will be safe custodians of the health of the community in which they practise.

If it be urged that the elective system in medical education will lead to the production of a class of physicians who, owing to the early specialization of their work, will be inclined to overrate the importance of their specialty and to see in every disease an opportunity for the display of their special skill, it may be pointed out that this result is apt to be due not so much to early as to imperfect instruction in the work of a specialist, and that since the elective system tends to encourage thoroughness in special instruction, the evil may be expected to diminish rather than to increase.

Methods of Instruction.—Having thus recognized the necessity of remodeling our conception of the subject matter to be taught and noted the importance of distinguishing between the essential and the desirable in medical education, we must next consider by what methods the needed information may be best imparted and the necessary training secured. There is, perhaps, no way in which modern educational methods differ more from those of an earlier period than in the greater prominence given to object lessons. Beginning with the kindergarten, the child is trained to cultivate his power to observe accurately and to manipulate skilfully and, through his school and college life, prominence is given to the objective side of education to an extent which would have seemed to the book-trained pedagogues of a former generation but ill-adapted to provide the well-stored mind which it was thought to be the principal object of education to secure. In the professional schools also the reaction against purely didactic methods has been strongly felt. Even in those professional pursuits to which the object method might seem at first sight least applicable, in the study of the law the so-called "case method" of instruction has been found to exert a vivifying influence.

In medical education in this country it is interesting to note that, in the very beginning, the instruction was more objective in its character than at a somewhat later period. In those early days it was in the office of his preceptor and at the bedside, as his actual assistant, that the embryo physician was initiated into the mysteries of his calling. Then followed a period when it was clearly perceived that the trained mind is necessary to interpret the data of observation and that mental training is essential to correct observing. Hence, schools were established to provide this training by means of systematic didactic lectures covering all the departments of medicine and usually extending over not more than four months. These schools were intended at first merely to supplement the work of the preceptors, but in process of time the relative importance of these two educational agencies was reversed and the work of the preceptors became supplementary to that of the schools. The function of the preceptors finally became so subordinate that their names no longer appeared in the catalogues, although this did not always indicate that they had ceased to afford students opportunities for practical clinical work.[12]

The schools, once established, grew chiefly by an increase in the length and number of the lecture courses as new and important subjects forced themselves on the attention of the medical profession. Against this undue extension of purely didactic methods of instruction a reaction has now set in and during the last ten or fifteen years loud voices have been raised in advocacy of more objective methods than those at present in use. It is not, however, the reinstatement of the preceptor that is urged, but rather the greater use of laboratory methods in the strictly scientific departments of medical instruction and their application as far as possible at the bedside of the patient. A discussion of the relative advantages of the laboratory, the lecture and the text-book as methods of medical education cannot be undertaken without a recognition of the fact that this education has a double object. In the first place the faculties of the student are to be so trained that he may observe carefully, reason correctly, study effectively and judge wisely; in other words, he is to be "trained for power" to use President Eliot's phrase. In the second place there must be imparted to him a sufficiently large fraction of the acquired medical knowledge of the time to make him a safe custodian of the health of the community. Which of these two objects is the more important is a question which we need not now discuss, but even if we grant all that is claimed by the advocates of training for power it is evident that the constantly increasing range of subjects with regard to which an educated physician must be informed will greatly reduce the time which, in the curriculum of a medical school, may properly be devoted to courses of instruction not intended to impart direct and valuable information. In fact, "training for power" should be largely a function of the academic department of a university, and when undertaken in a professional school, should be so directed as to impart at the same time the greatest possible amount of useful information.

Let us now consider how far the didactic and the laboratory methods of instruction are each adapted to secure these two objects of medical education. For the purpose of training for power no one can doubt the value of the laboratory method. Contact with the phenomena themselves and not with descriptions of them has a stimulating effect on the mind of a student, the

importance of which it is difficult to exaggerate, but it does not follow from this that the lecture, the recitation and the text-book are worthless as methods of training. It is here that some of the advocates of laboratory methods have committed what appears to me a serious error such as is too apt to characterize all reform movements, the error, namely, of assuming that, because one proposition is true, another proposition, not logically inconsistent with it, must be untrue. "These gentlemen," as Professor Howell[13] has expressed it, "having become possessed of the golden truth that the best knowledge is that which comes from personal experience, seem disposed to deny all value to knowledge communicated from the experience of others." We are told, for instance, by Dr. Burr,[14] that the didactic lecture "dates from the time when printing was unknown and manuscripts were rare and almost priceless and the only means of communicating knowledge was by word of mouth. To-day it is in large part an anachronism, because the time devoted to it could be put to better uses."

In his able address[15] at the last Yale University Medical Commencement my colleague, Dr. C. S. Minot, expressed himself as follows: "The very best that can be said of a lecture or a book is that it describes well the knowledge which some one possesses. There is no knowledge in books. . . . A book or a lecture can serve only to assist a man to acquire knowledge with lessened loss of time. Knowledge lives in the laboratory; when it is dead we bury it decently in a book. . . . A lecture is a spoken book." I venture to believe that Professor Minot's students will hardly agree with this estimate of the lifeless character of either his written or his spoken instruction.

In place of these rather disparaging views of the importance of a didactic lecture, I am inclined to accept Dr. Weir Mitchell's[16] opinion that "The best lecturing does not so much think for you as invite you to think along suggested lines of enquiry." If, as has been claimed, "the passive attitude of listening does not demand of the students intelligent thought"[17] the fault must lie with the lecturer and not with the method of instruction. In every department of medicine advanced instruction necessarily deals with subjects which lie within what Foster has called the "penumbra" of solid scientific acquisition and about which conflicting views are therefore certain to be held. It is in inviting thought with regard to the evidence on which these views rest that the experienced lecturer has his best opportunity to train the minds of his hearers. Other opportunities are also afforded by the historical presentation of subjects about which differences of opinion no longer exist, for there are few things more instructive than to follow up step by step the lines by which our knowledge has advanced, noting the marks which distinguish the paths which have been trodden successfully from those which have turned out to be "No Thoroughfare." Even better opportunities for mental training than those which the lecture room presents are afforded by the recitation, for here the minds of the teachers and the pupil are brought most closely into contact, the pupil's difficulties are appreciated by the instructor and the point of view of the teacher can be learned by the pupil. It has always seemed to me that no higher enjoyment falls to the lot of the teacher than that which he experiences when, by a series of carefully considered questions, he leads his pupil onward from the known to the unknown and notes the gleam of intelligence which illumines his countenance as a subject, previously obscure, becomes clear, as a result of his own mental operations guided by his teacher's skilful questions. It thus appears that no monopoly of opportunities for mental training can be claimed for the laboratory method of instruction.

We must next enquire: What are the relative advantages of the laboratory and didactic methods as means of imparting information? Here we at once perceive that a great deal will depend upon the kind of information to be imparted. Certain subjects are much better adapted than others to be taught in the laboratory. The student of anatomy, for instance, can secure the greater part of the information which he needs by laboratory methods, *i. e.*, in the dissecting room, although a short course of lectures on descriptive anatomy in which an experienced teacher emphasizes the salient features of the subject will probably always be indispensable. Physiology and Pathology (including physiological chemistry, pharmacology and bacteriology) are subjects in which laboratory instruction may be unquestionably much more freely used than is customary at the present time. The recent experience of the Harvard Medical School, in which the laboratory courses in these subjects have been greatly extended, has furnished conclusive evidence of the value of this method of instruction as a means both of imparting information and of stimulating the mind of the student. It must be remembered, however, that, as Dr. Welch[18] has said, "laboratory methods are extremely time taking and are not adapted to teach the whole contents of any of the medical sciences. It is, of course, hopeless to attempt to demonstrate practically all of even the more important facts that the student should learn."

Moreover, observed facts are often apparently inconsistent with each other. Equally competent observers differ in their interpretation of them. Yet, because the last word of science has not been spoken on these subjects, it would be a mistake to exclude them from the medical curriculum. The student should rather be carefully instructed as to researches which have not yet yielded definite results. The most profitable way of reconciling conflicting observations should be pointed out, and he should be shown in what direction the search for truth can be prosecuted with the best prospect of success. He will then be able to appreciate the value of new observations and to assign them to their true position.

Instruction of this sort can, of course, be given only by an experienced lecturer who has mastered the subject of which he treats. It is in this kind of teaching and in the exposition of those facts and principles which cannot properly be made the subject of laboratory instruction to students that the didactic lecture of the future will probably find its principal field of usefulness. In the latter direction, however, the field is more restricted than might, at first, appear, for the amount of practical work that can be successfully performed by first and second year students in a physiological or in a pathological laboratory is surprisingly large. In the physiological department of the Harvard Medical School, for instance, during the current academic year each pair of students in a class of 180 has been furnished with a kymographion, a capillary electrometer, a moist chamber, an induction coil, unpolarisable electrodes, etc., and the most important experiments of nerve muscle physiology have been successfully repeated. The fundamental experiments in the physiology of the circulation, respiration, etc., are to be performed in a similar manner. In the pathological laboratory the students, working in sections of ten, have had an opportunity of producing for themselves and studying experimentally the most important pathological degenerations. They have also studied in the same way the principal infectious diseases. In the anatomical department also, while the number of didactic lectures has been diminished, the whole class has had largely increased faculties for the practical study of bones and of various special organs.

Still, after making due allowance for the legitimate expansion of laboratory teaching, it is probably safe to say that a systematic course of lectures in each of the medical sciences will never be found to be superfluous and that the day is probably far distant when the lectures will be merely "explanatory of the experiments."[19]

We have thus far considered the relative advantages of didactic and laboratory methods in teaching the medical sciences, but the agitation in favor of more objective teaching has extended also to the clinical departments of medicine and the organization of "clinical laboratories," in which the cases of hospital patients may be studied by the most refined methods of physiologic and pathologic research, is a natural outcome of this agitation. In fact, however, so far as instruction is actually given at the bedside, clinical medicine has always been taught by means of object lessons. In many of our schools this instruction has been supplemented by so-called "conferences," exercises in which a student reports before the class a case which he has himself examined, giving diagnosis, prognosis and treatment. The subject is then discussed by the class and finally by the instructors.

Wherever actual cases of disease are thus utilized for teaching purposes the instruction is always likely to be more or less haphazard and unsystematic, for the diseases studied will be those of which actual cases happen to be available. To remedy this difficulty it has been recently proposed[20] to substitute the study of hospital records of cases for the examination of the cases themselves, a method quite analogous to that known as the "case-method" which has long been used with great success in training students in the Harvard Law School. It will thus be possible to group cases so that they will throw light upon each other and, though the student will miss the stimulus of contact with the actual patient, the method presents so many distinct advantages that it will doubtless commend itself to many teachers of clinical medicine and of theory and practice.

It is thus evident that the reaction against purely didactic methods of instruction is well under way. It is a movement to be heartily welcomed, for there can be no doubt that medical students have been and still are too much lectured, but, like all other reforms, it should be carefully guided lest useful as well as useless things be swept away. It should be borne in mind that it is quite as easy to abuse the laboratory as the didactic method of instruction and that in all schemes of education a good teacher with a bad method is more effective than a bad teacher with a good method. As Professor Howell[21] has well remarked, "courses of lectures, that, if analyzed would be found to be top-heavy and lop-sided, and otherwise possessed of an instability that should have insured failure, have been saved and made instruments of great value by the mere earnestness of the teacher."

Distribution of Work.—The next question which I shall ask you to consider is that of the proper distribution of the work of a medical student. Thirty years ago no such question seems to have presented itself to the minds of instructors in medicine. The medical faculties of that time contented themselves with providing, each year, courses of lectures covering all the departments of medicine, as they were then understood, and every student was expected to attend as many of the lectures as he saw fit. Between 1870 and 1880 the fact that there is a natural sequence in medical studies became generally recognized and graded courses of instruction were established in the principal medical schools of the country. The grading was not, however, carried sufficiently far. Thus instruction in both anatomy and physiology was generally given simultaneously through the whole of the first year, though the knowledge of structure should logically precede a study of function.

The time seems now to have come for taking another step in grading medical instruction and, during the academic year now drawing to a close, instruction in the Harvard Medical School has been given in accordance with a plan of which the guiding principles are concentration of work and sequence of subjects. Thus in the first half of the first year the students devote themselves exclusively to the study of anatomy, including histology and embryology. In the second half

year they are occupied with physiology, including physiological chemistry, while in the first half of the second year pathology, including bacteriology, engages their attention. It is perhaps too early to pass a final judgment upon the value of the method, but thus far both teachers and students seem to regard it as a success. The result seems to have justified the opinion of its advocates that the work of the student would be made "easier by concentrating his thoughts upon one subject instead of dissipating his attention upon many subjects."[22] Nor have its opponents found any justification for their fears that the average brain would become fatigued and unreceptive by too close application to one subject, for the sciences of anatomy, physiology and pathology "are not narrow hedged-in areas but rather broad and diversified domains composed of many contiguous fields,"[23] in passing from one to another of which the student may rest his mind without interrupting the continuity of effort essential to effective work.

An obvious objection to this method of concentrating instruction is the large amount of work which it imposes upon the instructors. There is no doubt that the labor of teaching every day in the week may task the powers of even the most enthusiastic instructor, but it has been found that the laboratory work which has occupied from two to three hours every forenoon has been conducted with much less fatigue than was anticipated. In fact, students, when supplied with printed directions for work and with the necessary apparatus, need remarkably little supervision. In the physiological laboratory it was found that one instructor could readily supervise the work of fifteen pairs of students, and the experience in the anatomical and pathological departments was of a similar sort.

Examinations.—Closely connected with the questions of method of instruction and of distribution of work is the subject of examinations. With regard to these tests of our educational methods opinions vary even more widely than with regard to the methods themselves. There is only one point, as Professor Exner has remarked, on which teachers are practically united and that is "that an examination is a necessary evil." Every examiner knows only too well that an examination is but a very imperfect test of knowledge, but few are ready with any suggestion of a substitute. Much of the confusion which prevails in the discussion of this subject would be removed if the objects to be secured by an examination were more clearly apprehended. Professor Exner[24] points out that examinations may be broadly divided into two classes, *viz.*, the *Controlprüfung*, to test the faithfulness with which the student has performed his daily tasks, and the *Reifeprüfung* to determine the amount of his permanently acquired knowledge of medical subjects.

The examination, which, at the end of the year, covers the whole ground of the previous twelve months' instruction and which is so common in our schools, belongs to neither of these two classes and is really a concession to a very natural wish of the student to get the examination "out of the way" while the subject is still fresh in their minds. Having little justification from an educational point of view, we may hope to see it abandoned when the extension of laboratory methods provides in the notebook and graphic records of each student the evidence of his daily work and thus either renders a further examination unnecessary or prepares the way for a final test of his fitness to receive his diploma of M.D. Whether the written or the oral examination affords the better method of applying this test is a question about which opinions vary. The fact that some persons can write more readily than they talk, while others can talk more readily than they can write, seems to be a reason for providing a mixed method of examination in which each individual may have an opportunity of appearing to the best advantage.

Conclusions.—If the views here presented are well founded we may expect that a medical school of the first rank will, in the immediate future, be organized and administered somewhat as follows:

I. It will be connected with a University but will be so far independent of university control that the faculty will practically decide all questions relating to methods of instruction and the personnel of the teaching body.

II. It will offer advanced instruction in every department of medicine and will therefore necessarily adopt the elective system of some sort, since the amount of instruction provided will be far more than any one student can follow.

III. The laboratory method of instruction will be greatly extended and students will be trained to get their knowledge, as far as possible, by the direct study of nature, but the didactic lecture, though reduced in importance, will not be displaced from its position as an educational agency.

IV. The work of the students will probably be so arranged that their attention will be concentrated upon one principal subject at a time and these subjects will follow each other in a natural order.

V. Examinations will be so conducted as to afford a test of both the faithfulness with which a student performs his daily work and of his permanent acquisition of medical knowledge fitting him to practise his profession.

If I have clothed these conclusions in the language of prophecy it is because the title of my discourse has laid this necessity upon me. In forecasting the immediate future, I have borne in mind the history of the immediate past, and, if I have failed to read aright the indications of the lines on which our medical schools are to advance, it must be remembered that the development of a biological science and of its dependent arts not infrequently takes place in totally unexpected directions, thus introducing into the

path of educational progress perturbations which may well defy prediction.

TRUTH IN MEDICINE.[1]

By E. G. JANEWAY, M.D.,
of New York;
President of the Association of American Physicians.

For the fifteenth time it devolves upon the President to welcome the members of the Association to that gathering which has its chief interest in meeting those engaged in like work. We will hear from them that which during the year past has seemed, of all that they have met and observed, the most fit to bring before colleagues interested in learning some new fact as regards the old diseases or some new interpretation of the phenomena of those maladies.

Fortunately we also have among our number those who are able to give themselves up to the study of pathology and from whom in the past we have learned much of the pathological processes which underlie disease, who will at this meeting continue their good work. Of late we have also been fortunate in having members who have given anxious thought to the chemical side of the study of the alterations of disease and who will again strive to enlighten us on this the most difficult of the questions with which we have to do. Each of us who has attended the past meetings must admit having received much of benefit from the presentations and the discussions of our associates. Your President of this year looks back with regret at certain of the opportunities which he wasted in the past, under the stress of his professional work, and he only alludes to it in passing that he may stimulate the younger members to so arrange the year that they may find the time to both give and receive knowledge, thus making the meetings of this association more valuable with each passing year. Let us each endeavor to make this Association so far as in us lies, as regards those matters which it falls under our province to consider, the equal of any and the inferior to none throughout the world. If we are each possessed by such a noble spirit of rivalry I am sure that our Association will not only maintain, but will surpass in the future that high regard in which it has been held.

Your President, in the fear that not enough of the members would bring material, sent out as you know two appeals. Results show that he was not sufficiently aware of the deep interest which you had in the success of our meeting on this the year of the Medical Congress. The calendar as you have read is more than full, and in so far as he may have been responsible for this the motto that brevity is the soul of wit is forced home upon his inner consciousness. It is his duty as well as his privilege to so allot the time that each member may be heard, and not himself to consume such time by his general introductory remarks as to infringe upon that which is the moral right of the members under the circumstances. But for this he would have been tempted to touch upon the theme "Truth in Medicine." This could have been handled under such heads as truth in statistics; truth in diagnosis; truth in therapeutics, and truth in pathology. Any society which has its annual meetings in the city of Washington, a city named after a man whose name could stand as a synonym for truth—should so far as its members are concerned, need no other reminder of the value of truth; nor do I think that the members of this Association need even this reminder for I take it we are all seekers after truth. Would that all who come to Washington could be so impressed by his name that only the truth should be spoken in this city, or only honest methods followed in the pursuit of power, place, and gain. But time urges and we now turn to the work of the Association.

[1] Opening Remarks of the President.

PERFORATING DUODENAL ULCERS.[*]

By ROBERT F. WEIR, M.D.,
of New York;
President of the American Surgical Association; Surgeon to Roosevelt Hospital.

The interest that has been lately directed toward the surgical treatment of gastric perforations has also been turned to the operative relief of the allied round or peptic ulcer of the duodenum. This affection is much rarer than the ulcer of the stomach, is much more difficult to properly diagnosticate, and is more apt to be confounded with other more distant surgical lesions, such as appendicitis, etc.

Its site is in the upper part of the duodenum, and according to Morot[1] and Vonwyl[2] it is always situated within one and one-half inches of the pylorus; but Schwartz[3] gives one case where the perforation existed on a level with or a little below the ampulla of Vater and thus allowed a free escape of bile into the peritoneal cavity. The figures given by recent authorities show that in the

[*] President's Address.

262 collected cases of Collin[4] the perforation occurred 242 times within 2 inches of the pylorus, in the descending portion, 14 times, in front of the aorta, 3 times, and in the ascending portion, 3 times. Or, expressing the same a little differently, 162 of the 262 cases were situated at 2-4 mm. from the pylorus; 75 close to it; 4 encroached on the pylorus itself, and 2 extended through the pylorus to the duodenum and to the stomach. Perry and Shaw[5] found in 141 cases of duodenal ulcer, 123 in the first part of the duodenum, 16 in the second part and only 2 in the third part.

Number.—These ulcerations are usually single. Collin says that one ulcer was found in 80 per cent. of his cases; two ulcers in 11 per cent.; and three or four ulcers in 4 per cent. Morot in 22 cases found that 18 had a single ulcer; two, 2 ulcers; one, 3 ulcers, and one, 4 ulcers.

Location.—These perforations are encountered most frequently on the anterior wall. Oppenheimer[6] in 15 cases noted that the perforation had taken place in the anterior wall 11 times; 3 times posteriorly and once superiorly. Of the 119 cases of Collin in which the first portion of the duodenum was perforated, in 68 it occurred on the anterior wall of the bowel; in 39 on the posterior wall; in 10 on the superior, and in 1 on the inferior portion. In 8 ulcers perforating in the second portion of the bowel, 5 occurred in the internal wall; 2 in the posterior and one in the external wall; and in the ulcers presenting in the third part of the duodenum, 4 in number; in 3 the anterior and superior walls were involved, and in 1 the posterior wall. This is of considerable surgical importance. The anterior perforations are, for obvious anatomical reasons, less likely to be closed off by adhesions and, hence, a free and rapid involvement of the peritoneal cavity takes place in openings here situated. Beckman[7] states that half the cases of duodenal ulcer die from perforation into the peritoneal cavity.

Perforation is said to take place 180 times in Collin's 262 cases, or in 69 per cent.; Chvostek, however, places the frequency of perforation at about 42 per cent. of the cases. In these 262 cases there was a generally diffused and fatal peritonitis, 125 times. Occasionally in anterior openings, but more commonly with the perforations existing elsewhere, adhesions or ulcerations with abscess and hemorrhage of the duodenal wall or adjacent organs have been encountered. Examples of such complicating lesions are subphrenic abscess which follows more commonly a perforation in the superior wall of the horizontal portion of the duodenum (according to Oppenheimer). Liver and pancreatic adhesions are at times met with (Oppenheimer gives 6 cases and Collin 38 cases of such adhesions). Perforations into the gall-bladder have been reported, but more important and dangerous are the ulcerations into the aorta (Stich[8] 2 cases), or the vena porta (2 cases, Rayer and Habershon), or the superior mesenteric vein (Warfinger), or the hepatic artery (Vonwyl). The ulceration has been also known to invade the adjacent colon (2 cases, Murchison and Saunderson).

Sex.—These perforations are more common in men than in women, about 79 per cent., according to Collin, occurring in males. From the tables of Morot, Kraus, Lebert and Chvostek I have gathered 176 cases of duodenal ulcers, and of these 144 were in men and 30 in women. This has been explained by Boas[9] to be due to the rougher food eaten by men and to their addiction to alcohol and tobacco.

Causes.—A coarse diet and alcoholic liquor, he thinks intensifies the acidity of the gastric juice and this acts unduly on the granular mucous membrane of the duodenum, which is not protected until the alkaline bile and pancreatic fluid is poured into the intestine at the opening of Vater. Koch and Ewald, by giving to animals 5 per 1000 HCl, caused duodenal ulcers to appear. Pyloric spasm, Talma states, produces necrosis and anemia of the membrane there. On the other hand, alcoholics are not found to be prone to duodenal ulcer, and although the spasms and lesions of gastric hyperacidity which are now accepted as a causative of stomach ulcer will doubtless apply in many instances to the development of a similar duodenal damage, there are other causes for duodenal ulceration to be mentioned in addition to the foregoing.

The principal and best known, although now somewhat disputed factor in their etiology is the influence of external *burns*. Holmes,[10] for instance, states that in 125 cases of burns, 16 cases of duodenal ulcer were found; Perry and Shaw in 149 cases of burns, met with duodenal ulcers five times; and in Collin's 297 cases of duodenal ulcer he states that burns produced the ulceration in 38 instances. According to Holmes the duodenal ulcerations after burns present themselves from the seventh to the fourteenth day, but Porfick found in one instance a duodenal ulcer within 18 hours after the reception of the burn. Curling also had a case where symptoms of duodenal ulcer were recognized one day after the burn, and the autopsy confirmed the diagnosis.

The explanation most accepted at the present day is that this complication of a burn is due to septic infarctions such as may be developed in frost-bite, of which Billroth and Adams each cites a case, or in erysipelas, 8 instances, or in tuberculosis (Latham). In the case where trichinosis (Ebstein), or heart or kidney disease, or cirrhosis or hepatic or other carcinomata (Latham) exist, it is not quite so easy to trace the connection, although even here thrombosis has largely to deal with the question. The recognized explanation offered by Hunter,[11] and often quoted, seems inadequate to elucidate the relation between a cutaneous burn and a duodenal ulcer. This observer proved that in animals treated by injections of toluylendiamene the bile was so changed that when discharged into the duodenum ulcerations rapidly developed. His idea, therefore, was naturally that the alteration of the cutaneous covering so altered the bile as to beget the compli-

cating duodenal ulcerations. Unfortunately, duodenal ulcers are so rarely met with on a level with or below the bile discharge into the bowel that this at once disposes of the need of calling on the liver and pancreas as accomplices in their production. That septic infarction is the most probable cause of duodenal difficulties after burns may also be fairly inferred by the later collection of Lockwood, in which, in 138 cases of burns treated with more or less approach to antiseptic idea, the complication of duodenal ulcer was noted in but one instance. A cancerous ulceration is almost unknown, but 4 cases (Eichert, Ewald, Schrotter, and McKenzie) are recorded.

Frequency.—According to statistics, a duodenal ulcer is a rare lesion. Collin, whom one is compelled to quote by the worth of his collected cases, could find only 26 cases in a range of 10 years. Houze[12] in three additional years could add only three more cases, although Darras[13] more than one year later found 5 others. Since attention has been given to the subject and particularly to the surgical aspect of it by the present writer in 1896, when 9 cases were reported as having undergone surgical treatment, there have been reported 41 operations for this disease.

The relative frequency as a cause of death deduced from autopsies is as follows:

Willigt, 1600 sections with 74 gastric ulcers and 2 duodenal.

Starke, 384 sections with 36 gastric ulcers and 3 duodenal.

Grunfeld, 1150 sections with 124 gastric ulcers and 4 duodenal.

Can be supplemented by:

Stein's 3085 sections with 89 gastric ulcers and 12 duodenal.

Vonwyl's 12,806 sections with 98 gastric ulcers and 3 duodenal.

Latham's 8192 sections with no gastric ulcers and 12 duodenal.

Perry and Shaw's 17,652 sections with no gastric ulcers and 70 duodenal.

New York Hospital (unpublished), 1000 sections with no gastric ulcers and 2 duodenal.

Total, 49,369 sections with 421 gastric ulcers and 108 duodenal.

Or about .2 per cent. in frequency.

Kinnicutt,[14] however, in 30,000 autopsies which probably included many embraced in the above table, has given a rather higher percentage of frequency, placing it at 0.4 per cent. Although the proportion is a small one, stress must be laid on the fact that from 40 to 70 per cent. of these ulcers perforate, with an almost invariable fatal result. The relative proportion of gastric to duodenal ulcers is 12 to 1, Butwinkel.

Age.—It is encountered at all ages. Chvostek in 87 autopsies on children under 10 years of age found 5 duodenal ulcers, of which 1 was seen in a 7 weeks-old child, another in a child 4 days old, and a third in a babe of 3 hours. Collin's table is the most complete in this respect, and it is here presented. In 297 cases of duodenal ulcers they were met with:

Under 10 years of age, 42 times.
Between 10 and 20, 24 times.
Between 20 and 30, 43 times.
Between 30 and 40, 52 times.
Between 40 and 50, 46 times.
Between 50 and 60, 41 times.
Between 60 and 80, 28 times.
Between 81 and 95, 3 times.

Progress.—It has already been stated strongly that nearly all perforations of the duodenum will prove fatal from a generalized peritonitis unless surgical intervention should relieve the patient. What this consists of, what are its results and its difficulties, will be considered a little later. At present one must take account of the somewhat encouraging fact that all duodenal ulcers do not go on to this severe complication of perforation. At 70 autopsies, Perry and Shaw found decided evidences of repair in nearly 50 per cent. of the cases, and Collin also recorded 39 instances of cicatrized ulcerations. These cured ulcers may prove innocuous but they can, as in the stomach, narrow to a dangerous degree the lumen of the intestine and even encroach on the bile opening, or make such traction on it as to bring about gastric and hepatic dilatations. Some of the most brilliant surgical triumphs have been obtained in relieving such obstructions.

Symptoms.—As shown by Schwartz, symptoms of a non-perforated duodenal ulcer are frequently very slight. In 20 out of 25 instances of perforation the patients were in apparent good health or so slightly indisposed that they had not consulted a physician. In only 5 patients were there previous stomach symptoms; of these one was thought to have dyspepsia, and two to have a gastric ulcer. In my own collection of 51 cases, treated by operation gastric symptoms previously existed in 25 out of 34. The usual signs may be given as follows:

Pain, when characteristic, occurs several hours after eating and may be slight or severe and present itself just below the gall-bladder and may reach to the median line or to a level with the navel. Many times the pain is absent. Beckmann in 80 cases found 16 in which little or no pain existed. Pressure, particularly over the region to right of the twelfth thoracic vertebra, occasionally elicits pain. Swallowing of a sour lemonade or a strong alcoholic drink may arrest the pain by bringing about a pyloric contraction, but Pagenstecher[15] denied the value of this test.

Vomiting is present in about 17 per cent. of the cases but it is of a reflex character. It is of diagnostic importance if, like the pain, it shows itself from an hour or so up to several hours after a meal and the matters rejected are broken-down food often mixed with bile and blood. The right shoulder pains are noted by Schwartz as occasionally to be recognized. According to Vonwyl and Buequoy, the pains are often slight from the comparative immobility of the duodenum and vary from queer indescribable sensations to severe radiations of distress. Vomiting when it occurs relieves the pain.

Jaundice if present, which is rare, may be due to simple duodenal tumefaction or to cicatricial contraction of the papilla.

Hemorrhage is to be expected in about one-third of the cases of non-perforating ulcers. Probably it is even more frequent than this as Oppenheimer found blood in the stools of one-half of his 34 cases, and Krauss says it occurs even more frequently than in this ratio. This bleeding can be severe and show itself by mouth as well as per rectum. It can speedily prove fatal as larger vessels are opened than by a gastric ulcer. Usually the blood is discharged from the bowels in a tarry condition which bespeaks a high origin of the hemorrhage and an exposure of some duration to the action of intestinal secretions. This is spoken of as melena. Its color may be, however, a bright hue, and recently, with Dr. Peabody, the question of the presence of a duodenal ulcer in a patient with intestinal hemorrhage and right-sided epigastric pain and distress sometimes after eating was negatively decided because the blood discharged per anum was of a bright red color and unclotted. As the patient, moreover, had hemorrhoids the possibility of this origin led to the confusion in diagnosis. This escape of fresh blood unchanged in the bowels is recognized by Vonwyl and some emphasis should hereafter be placed on this possibility. The profusion of the hemorrhage may be much beyond that encountered in gastric ulcer, for larger vessels may be involved. Collin gives 12 instances in which the blood came from the pancreo-duodenal artery; three times the gastro-epiploica dextra was opened into; twice, the pancreatic artery; the aorta twice; the vena porta twice; the hepatic once; and once the superior mesenteric vein. Pagenstecher states that the ulcers on the posterior wall are more apt to bring about hemorrhage than the anterior ones as the vessels are more abundant and larger there. Burwinkel[16] says that, excepting in vicarious menstruation and typhoid fever, intestinal hemorrhage in large amounts is very rare and should excite suspicion of gastric or duodenal ulcers. This writer, in spite of all that has been advanced by Nothnagel, Ewald, Lemke, and latest of all, Kinnicutt,[17] that in the great majority of cases a differential diagnosis from gastric ulcer is impossible, claims that by a careful study of the symptoms he has been able to diagnose 5 cases of duodenal ulcers in the last five years.

The following contrasting symptoms have been grouped by Vonwyl as an aid to this end: *Gastric ulcer:* (1) More frequent in woman, 25th-50th year. (2) Pain promptly after eating. (3) Relieved by vomiting. (4) Frequent biliary, mucous, and food vomiting. (5) Marked dyspeptic symptoms. (6) Frequent bloody vomiting. (7) More seldom bloody stools. *Duodenal ulcer:* (1) Occurs most frequently in males. (2) Pain in right hypochondrium or to the right of parasternal line. (3) Comes on 2-4 hours after meals. (4) No relief by vomiting; latter not frequent. (5) Bloody stools (melena or bright blood) more common than bloody vomiting. (6) If jaundice is present this would contribute to the diagnosis.

That medical and surgical education in this line is progressing has also been brought out in the cases of operations which form the basis of this paper. Here it will be seen that, notwithstanding that the greater part of them have been treated as of appendical or other origin, surgeons, awake to the possibilities of the case, are making shrewder diagnoses and the reproach which was good up to a year ago, that no operation for a previously recognized perforated duodenal ulcer had yet been performed, no longer holds good. It may be expected that as the detection and treatment of a perforated gastric ulcer has so rapidly and so satisfactorily progressed, from 1892, when the writer was only able to add to his first operation of this kind but 4 other instances, while now over 100 cases each year are operated on with a mortality that has fallen (if operated on within 12 hours) from 39 per cent. to 17 per cent. (Keen[18]). The picture is a far different one when the duodenal ulcer perforates, and, anteriorly, which is the most common site of this complication. Here there is usually no withholding adhesion, and a rapid invasion of the peritoneum is probable.[19] If the stomach is yet filled, the extravasation may take an anatomical course somewhat in the order spoken of by Pagenstecher, and which is in accord with my own analogous clinical experience in 3 perforations of the gall-bladder. Fluids escaping from the duodenum or gall-passages flow at first between the liver and the colon and thence along the ascending colon toward the iliac fossa; from this point it may pass over to the sigmoid flexure or into the pelvis. Given, therefore, such a free course and with a plentiful pouring out of an acid fermenting food and gas through a direct although small (2 to 8 mm.) opening, the symptoms presented would naturally be severe.

Great *pain* is usually felt at the epigastrium or to the right of this region. As was noted here 26 times in 47 of my cases, it has a few times been observed at the umbilicus and in the left side; but in 23 others of the 47 instances it was simply recorded as abdominal pain. Vomiting often follows the attack of pain. It occurred in 28 out of 34 instances. Shock is not often met with but may be severe and fatal. Peritoneal symptoms rapidly develop with a tendency in some cases to be localized in the upper part of the abdominal cavity and in the right side; when these signs show themselves mostly to the right and at or below the level of the umbilicus, the picture necessarily simulates an appendicitis. When the liver dulness has been dissipated up nearly to the mammary line, air extravasation may be suspected, and, when accepted as present, it will aid in concentrating the diagnosis. The symptom of liver resonance, unless marked, is so often found to be due to a distended colon that it should not be much relied on.

In considering the diagnosis of a perforated duodenal ulcer as just given, I cannot but feel

that more weight and attention should be given first to the previous history, which shows, contrary to the opinions of many previous observers, that in the 51 collected cases of operations for the relief of such conditions there was a history of gastric or dyspeptic symptoms given in 25 out of 34 instances, where this point was noted; secondly, and also important, is the fact alluded to on a previous page that the initial or early pain was developed in 26 instances out of 47 in the epigastrium; and in the right hypochondrium 13 times. The third factor of value in the diagnosis, as well as the treatment of the symptoms of perforation peritonitis, whether from stomach, duodenum, gall-bladder, appendix, or any other part of the intestinal tract, is the early resort to an exploratory incision. This need of an early solution of the site of a perforation has been clearly shown in the cases of a gastric perforation in an article[20] embracing 78 cases operated for this trouble. The mortality clearly depended on whether the patient underwent surgical intervention within 24 hours from the inception (*i. e.*, the pain) of the perforation. This is yet more strongly marked in the latest collection of this class of troubles by Mayo,[21] who states that in 429 cases of gastric perforations those operated on in the first 24 hours were 82 where 47 recovered; 35 died (42 per cent.); and that in operations done after that period over 70 per cent. of the cases died. In duodenal perforations the same outcome is observable. In the 51 collected cases of duodenal ulcer perforations herewith presented, there were 25 cases where the lesion was recognized and closed at the operation; of these, 13 underwent operation after 30 hours delay and all died; of 12 others operated on within that time 8 survived, giving thus only 33.3 per cent of mortality. *Only*, I say and with much satisfaction, since it marks an improvement on the statistics of Pagenstecher, which gave a mortality of 60 per cent. in the found and sewn up duodenal ulcers that he had collected. Of equal value as illustrating the increasing alertness of the surgeon is the fact that prior to 1895 in the 28 cases reported up to that time in which laparotomy was done, in 15, or 75 per cent., the ulcer was not found; in 5, or 25 per cent., it was found and sutured. In only 2 cases, or 10 per cent., was the possibility of a duodenal perforation considered. Contrast this with the 31 cases operated on since 1895, when the surgery of gastric ulcer began to be developed. Of these 31 cases the perforation was not found in only 11 per cent. It was found and sutured in 20 cases, or 65 per cent. Its presence was considered in diagnosis in 11 cases, or 35 per cent.

Another indication showing the advance in surgical art is the circumstance that it has been possible in 13 of the more recent instances to either arrive at a correct pre-operative diagnosis or to make the alternative diagnosis varying between a duodenal and a gastric perforation. The difficulties that have been experienced are succinctly shown in the following statement:

Diagnosis Wrong: Ulcer Not Found.—Diagnosed as acute peritonitis, 8 times; as appendicitis, 15 times; as intestinal obstruction or appendicitis, 1 time; as strangulated hernia, 1 time; as hydronephrosis, 1 time; making a total of 26.

Diagnosis Wrong: Ulcer Found.—Diagnosed as acute peritonitis, 5 times; as intestinal obstruction, 4 times; as appendicitis, 3 times; total, 12.

Diagnosis Right or Approximately So: Ulcer Found.—Diagnosed as duodenal ulcer, 5 times; as gastric or duodenal ulcer, 6 times; as appendicitis or duodenal ulcer, 2 times; total, 13.

For the treatment of a duodenal ulcer the medical means applicable to the management of a gastric ulcer also hold good. It is but seldom that surgical aid is called for before perforation has occurred, but the cases reported by Codevilla[22] are of much surgical interest and instruction. This surgeon, for the relief of symptoms that fairly well pointed to an intractable duodenal ulceration, resorted to a gastro-enterostomy in two cases with a cure as the result of his intervention.[23] In some cases of perforation the shock and progress of the infection are so rapid as to bring about death in a few hours. Stevens[24] quotes a case where a fatal issue occurred within 21 hours after the first symptom (sudden pain) had shown itself.

Where the diagnosis has happily been narrowed down to a perforation of either the stomach, duodenum or gall-bladder, the incision to be advised is in or along the edge of the rectus muscle, 4-6 inches in length, and starting rather low down on the abdominal wall, so as not to reach much above the liver edge, but to extend far enough downward to easily get below the transverse colon which might be necessary. Supplementing this incision in its upper third, another transverse one in the skin to the left or toward the median line is advisable. This will permit the cross division of the fascia covering the right rectus muscle, which is in turn to be pulled to the left when its posterior sheath with the peritoneum is also to be divided. This gives a satisfactory and largely increased exposure of the parts beneath, and the subsequent suture of the upper and lower sheath of the rectus, with the full replacement of the muscle, adequately restores the integrity of the abdominal wall. This incision I have used many times in operations on the gall-passages and in numerous instances of suppurating appendicitis when increased space was necessary.[25]

If gas or food material escape when the abdomen is opened the surgeon's action is rendered more certain, and a rapid and thorough inspection, after wiping away any obscuring fluid, of the gall-bladder, duodenum and the anterior walls of the stomach, can be disclosed. If nothing is visible in these regions, the examination of the posterior gastric wall can be accomplished by either tearing through the gastrocolic omentum, or by turning up the omentum and large

bowel and entering the lesser omental cavity through the mesentery as in posterior gastroenterostomy. From the lower end of this wound, which is large enough to admit the hand, in many instances the appendical region can be explored if it should be necessary, although probably if this should be involved a separate incision might be more suitable. If a duodenal perforation exist it will generally be found on the anterior wall of the duodenum as a small round opening, rarely beyond one-fourth of an inch in diameter, with comparatively thin edges and rarely adherent to any adjacent intestine. Gas or fluids have frequently been seen passing from the opening and occasionally bile, which latter may also stain the peritoneal extravasation. Mayo has suggested that an acid reaction of the peritoneal effusion might help in suggesting, prior to its discovery, a gastric or duodenal opening, but, as the inflammatory effusion rapidly neutralizes the stomach acidity, this will seldom be of help.

Since several of the collected cases have shown in the abdominal extravasation the presence of recognizable medicines, such as castor oil, etc., given erroneously to move the bowels, it may be considered worth while to utilize the fact and to give prior to the operation a certain amount of methylene blue or other innocuous colored solution to aid in the detection of the opening. When found, the perforation should be closed by a double or triple row of interrupted sutures. No attempt should be made, in my judgment, to excise the ulcer before suturing. This takes too much time, and the results in the collected operations show that in 7 out of 9 of the successful cases suturing alone was relied upon. In one only was excision and suturing employed, and in one other case the ulcer was closed over by suturing over it the duodenum, colon and stomach. This experience is confirmed in the large number of gastric perforations that have been treated up to date.

The suggestions given by Pagenstecher for the conduction of this operation are worthy of remembrance. They are that the fundus of the gall-bladder when distended lies in front of the duodenum. By raising up the transverse colon, which rests somewhat in front of and below the horizontal part of the duodenum and by drawing it forward, this portion of the intestine is immediately revealed. Crowding the stomach and pylorus to the left and a little downward with lifting up the liver and pushing the colon down, a good view of the locality of a perforation is obtained.

The closure of the perforated intestine, however, leaves much of the battle for life unfinished. The proper and systematic cleansing of the peritoneum is of the utmost importance. If the extravasation is limited, careful wiping out of the affected portion of the peritoneal cavity with especial attention to the retrogastric and suprahepatic spaces and to the splenic and renal region, with ample gauze drainage will in most cases suffice better than the large warm irrigations of sterilized salt solutions which are, I think, more suitable in extensive or general peritoneal inflammations.

For those who favor multiple incisions and large irrigations the specific directions of Lennander[26] are of value. In suitable cases and in patients of sufficient vitality, he considers that irrigations with water at 104° F., through several incisions, the best method of cleansing the peritoneal cavity. One must go carefully and methodically about the solar plexus and the diaphragm; methodically loosening adhesions, irrigating, and then wiping clean with wrung-out gauze. He begins with the upper surface of the liver, particularly on both sides of the suspensory ligament; then passes between the liver and stomach to the triangular ligament; then around the cardiac portion; then between the stomach and spleen; then under the diaphragm to the left kidney, and along the spleen to the ligamentum phrenocolicum. The division of the triangular ligament with a thermocautery has been suggested, so that one might sweep around the left lobe on both sides. He then cleans between the right kidney and liver, kidney and colon, colon and liver; next the lumbar regions and both iliac fossæ; then both sides of the mesentery of the small intestine, and last the pelvis, which is often infected at the beginning of the trouble. A great quantity of hot fluid is of undoubted benefit in the pelvis. Drains and tampons are intended to remove accumulating fluids as well as to shut off infected areas. Tubes surrounded by gauze are the best drains. He places sterile gauze on both sides of the suspensory ligament of the liver and between the liver and diaphragm. Drains should be placed in both lumbar regions, the left passing alongside of (better through) the phrenocolic ligament external to the spleen to the middle of the diaphragm. The right one passes to the duodenum. The pelvis of men is drained above the symphysis pubis, that of women through the vagina.

My own experience in the surgical treatment of duodenal perforation is confined to one case which is briefly as follows:

Perforation of Duodenal Ulcer; Laparotomy; Suture; Death.—Man, aged thirty years, who had previous symptoms, confusedly detailed, of gastric disturbance but not of hematemesis for several months, was seized 4 days previously with severe epigastric pain, chill, fever, repeated vomiting and great prostration. No blood expectorated or dejected. His abdomen rapidly swelled and became generally tender and painful. On entrance into the New York Hospital, April 30, 1899, nothing could be made out by palpation save that the liver dulness was nearly obliterated. The abdomen was very tympanitic and no special point of tenderness or dulness was observed. He also had a double hernia. On the right side there was a protrusion of intestine beyond external ring. The pulse was 140, and

the temperature 104° F. Diagnosis, a general peritonitis from a gastric or duodenal perforating ulcer was made. A large median incision was made with the umbilicus in center for general exploration. The fingers showed nothing at the rings or at the cecum, and then, on carrying the examination upward, a minute, sharply-defined perforation, one-fourth in. in diameter, was found on the anterior wall of the duodenum near pylorus, out of which was oozing some brandy and water given just before chloroformization. This was sutured with a double row of Lembert sutures and peritoneal cavity systematically and carefully washed out with sterile salt solution. The patient was returned to the ward in bad condition. Salt transfusion, 75 oz., etc., were employed, but the patient succumbed shortly after the operation.

The autopsy showed the perforation to be in the duodenum just below the pyloric termination and in its superior anterior wall. Within the bowel was a deep ulcer at the bottom of which had occurred the perforation.

Later Effects of Duodenal Ulcer and Operation for Same.—There yet remain a few words to be said about the late consequences of a healed duodenal ulcer. The resulting cicatricial contraction may bring about stricture of the duodenum and dilatation of the stomach, and may by traction or primary ulceration damage the bile entrance to the intestine. Several interesting surgical cases have been reported where relief has been afforded by such circumstances. Pagenstecher quotes a case by Lange[26] where a gastroenterostomy was successfully resorted to for contraction of the duodenum, to the hardness and size of the finger, 3 c.m. from the pylorus with dilatation above of the duodenum and stomach.

Codevilla[27] details a more acute case with ulcer and stenosis of the duodenum and dilatation of the stomach. The duodenum was found at the operation markedly stenosed, as in Lange's case, and a gastroenterostomy was performed with a successful and permanently good result.

Carle[28] had a similar case in the front part of the duodenum, but the gastroenterostomy resorted to ended fatally. He also reported another instance where great emaciation and stomach dilatation demanded surgical interference. The first and second parts of the duodenum were found strongly contracted but with atrophic thin walls. Gastroenterostomy was employed with success; death one year later from lung tuberculosis.

Rewidzow[29] also cites a case which is doubtfully placed among these, as the locality of the stenosis following bloody vomiting and gastric disorder for 20 years was shown at the operation to be below the bile papilla where a stenosis existed. For this a gastroenterostomy was successfully resorted to.

[19] It should also be remembered that generally the duodenum in its first part is free and covered by peritoneum, so that extravasation is likewise possible through a perforation in this region. It is, however, more likely to enter the omental bursa (lesser omental cavity) or invade the retro-peritoneal tissues.

THE PRESENT STATUS OF RECTAL SURGERY.[1]

BY JOSEPH M. MATHEWS, M.D., LL.D.
OF LOUISVILLE, KY.;
PRESIDENT OF THE AMERICAN PROCTOLOGIC SOCIETY.

PERMIT me to thank you for the honor that you have conferred upon me in electing me to the position of presiding officer over this, your first meeting as an organized body. For over twenty years I have been impressed with the importance of the affections which you are here to discuss, and it is very meet and proper that an association should be formed bearing the name of this one. During the time mentioned I have seen this important branch of surgery wrested from the hands of the quack and pretender and placed where it rightfully belongs—and to-day no book on surgery is complete unless a fair exposition of the merits of proctology is given. Every special work, whether dealing with disease from a medical or surgical standpoint, must contain a chapter devoted to these diseases. The general surgeon, who in the past gave but slight attention to their consideration, recognizes the importance now of giving to them more careful attention, in order to be successful in their treatment. The practitioner of medicine has come to realize that the many diseases which fall under this head are not only often distressingly painful, but may endanger the life of the patient; that many conditions, puzzling in their nature, may exist, which can be accounted for by reflex action from this part of the body. Some men of ability have deemed this class of disease of sufficient importance to make their treatment a specialty, while others combine their consideration with

some other branch of surgery for special consideration. This, I say, is very gratifying to me in that for many years it has been a pleasant duty with me to plead for their recognition by the regular profession.
